Abstract  Due to high swelling-shrinkage caused by climate change, expansive soil is a significant problem in light construction, road embankments, and slope stability (wet and dry). The physical and mechanical properties of the soil are affected by repeated drying and wetting cycles, particularly changes in volume, negative pore water pressure (suction), and compressive strength. Fly ash is used to increase soil strength and reduce plasticity caused by swelling to address this issue. Because of its chemical properties, fly ash is an excellent choice for low-cost soil improvement. The purpose of this investigation is to determine the static mechanical properties of expansive soil fly ash stabilization under Proctor standard compaction conditions. Mechanical properties were investigated due to changes in soil moisture content, saturation, suction, and compressive strength caused by repeated drying and wetting cycles. The soil's suction was measured using Whatman #42 filter paper, and the soil's compressive strength was tested using a free compression test. According to the findings, the fly ash mixture altered the expansion and shrinkage behavior of expansive soils by lowering the consistency limit. At the same moisture content, the addition of 5% to 15% fly ash increases the compressive strength of the soil significantly. Compressive strength (q_i) and stress-strain modulus (E_i) decreased in 1-4 cycle cycles, and after four cycles, changes in compressive strength and stress-strain modulus were very small or insignificant. The proposed method effectively reduces the loss of expansive soil strength caused by environmental changes (wetting-drying). As a result, it contributes significantly to the development of materials to reduce structural damage in expansive soils.

Keywords  Expansive Soil, Unsaturated Soil, Fly Ash Stabilization, Wetting-Drying Cycles, Unconfined Compression Strength

1. Introduction

Expansive soil is one of the most common problems encountered in the civil engineering sector. The expansive soil issue has resulted in considerable losses, particularly in light structures or constructions and roads [1], [2]. In the United States, the losses caused by the expansive soil problem outnumber those caused by any other natural disasters, including earthquakes and tornadoes [3], [4]. In terms of soil distribution, expansive soils can be found throughout Indonesia, from North Sumatra to Papua [5], [6].

The soil in the tropics is constantly drying and wetting due to the alternating rainy and dry seasons. Repeated drying and wetting cycles will cause physical and mechanical properties to change [7]. Mixing fly ash with expansive clay is one method of chemical stabilization.
The availability of this material rises in tandem with the number of PLTU developments that use coal as fuel [8]. Several previous studies on the effect of repeated drying-wetting on soil mechanical properties concluded that the number of repetitions of the drying-wetting cycle and the degree of drying affected the decrease in compressive strength. The compressive strength decreases as the number of repetitions of the drying-wetting cycle increases. However, after six cycles of six repetitions, the change in compressive strength did not show a significant change [9]–[12].

Meanwhile, the use of fly ash for soil improvement has proven to be highly effective [13]. The plasticity index, optimum moisture content, swelling rate, and swelling pressure increased as the proportion of bentonite increased and maximum dry density decreased. The more fly ash there is, the lower the plasticity index, density, swelling rate are, and swelling pressure. The optimal proportion of fly ash is 5%, which significantly reduces the rate of swelling pressure. The addition of fly ash to swollen soil improves the engineering properties of the soil [14]. Another finding revealed that adding 20% fly ash to the clay significantly increased the soil's strength. Aside from fly ash, many studies have been conducted to improve the strength of expansive soils using other additives. The addition of cement kiln dust (CKD) raises the soil properties index. The addition of 10% CKD significantly increased the soil's compressive strength and bearing capacity (CBR). Expansive soil improvement with CKD can improve the subgrade of lightly travelled roads and as an admixture in lime stabilization during the construction of flexible pavements on expansive soils [2]. Furthermore, various additives to improve expansive soils' strength and bearing capacity have been extensively researched and well documented [15]–[18].

Based on previous studies on the improvement of expansive soils as a guide, this study determined the characteristics of the compressive strength of expansive soils by stabilizing fly ash on the behaviour of environmental changes by modelling repeated wetting-drying. As a result, the objective of this study is to investigate the effect of adding fly ash on soil plasticity and strength, specifically the negative pore-water pressure and compression strength of the compacted expansive soil due to wetting-drying cycle repetition. The study's findings provide a comprehensive overview of expansive soil properties stabilized with fly ash as an alternative construction material and contribute to the future advancement of material engineering technology.

2. Materials and Methods

2.1. Expansive Clay

The expansive clay in this study was obtained from Tabona, Ternate City, with the sampling point located at 0°46'33" N and 127°43'21" E, as shown in Figure 1. Following that, the clay was mixed with commercially available Bentonite to produce a moisture content of 198%, indicating that the mixed soil has high plasticity according to the unified soil classification system (USCS) [7]. Fly ash obtained from the Tidore power plant was added at a rate of 5% to 15%, depending on the weight ratio.

![Figure 1. Clay soil sampling location](image-url)
2.2. Sample Preparation

Before the pulverization process, the clay soil is dried in air-dry conditions. To make a clay-bentonite mixture, first, weigh the required amount of clay and bentonite with the total dry weight of the sample and mix it in a dry state. Water is added to the soil mixture to achieve the best moisture content for compaction results. Manual mixing is used to homogenize the mixture. At each stage of mixing, to achieve a homogeneous mixture. The mixture's water content was determined using the Standard Proctor ASTM D 698 (1995) test results [19]. The drying-wetting experiment is repeated on a cylindrical sample with a diameter of 36.5 cm and a height of 12 cm created with a PVC mold.

2.3. Atterberg Limits and Compaction Tests

The soil consistency of clay and mixed soils was determined, and the liquid and plastic limits were tested under ASTM D 4318 (1995) [19]. The optimum moisture content was determined according to the standard Proctor following ASTM D 698 (1995) [19], to prepare the sample for the wetting-drying cycle test.

2.4. Wetting-Drying Cycle Test

This test is used to determine how mixed soils' physical and mechanical properties change. Before testing, all samples were kept for 24 hours. This procedure entails lowering and raising the percentage of water until it reaches a predetermined level of water content. The water content is reduced from the optimum moisture content to a dry content of 25%, 50%, 75%, and 100% (drying path), and the water content is added from the dry water content to the optimum moisture content (wetting path). The entire procedure was repeated six times. Previous studies found no difference test results after the fifth drying-wetting cycle [20]–[23]. Table 1 and Figure 2 summarize the drying-wetting process model for all compacted samples, modified based on previous studies findings [7], [12].

| Process stages | Drying-Wetting (Compacted Initial Condition) $w_i=w_{opt}$ |
|----------------|----------------------------------------------------------|
|                | Kadar air                                                |
|                | $w_{opt}$ | 25% | 50% | 75% | 100% |
|                | 5%FA      | 15%FA | 5%FA | 15%FA | 5%FA | 15%FA | 5%FA | 15%FA |
| Drying (%)     | 26.8      | 23.7 | 20.1 | 17.8 | 13.4 | 11.8 | 6.7 | 5.9 |
| Wetting (%)    | 0         | 0    | 6.7 | 5.9 | 13.4 | 11.8 | 20.1 | 17.8 |
|                | 26.8      | 23.7 |    |    |    |    |    |    |

Figure 2. Dry-wetting repeat experimental test (modified after Maekawa and Miyakita, 1991; Saing, et al., 2020)
2.5. Soil Suction Measurement Method

*Whatman #42* filter paper was used to measure negative pore pressure (suction). When compared to other methods, this method has a relatively broad measurement range. To avoid contamination of each coated filter paper on the top and bottom, three filter papers with a diameter of 2.7 cm and placed on the top, middle, and bottom fitted on each sample. The water content of the filter paper and thus the value of soil suction are calculated using a calibration graph [24]–[27].

3. Results and Discussions

3.1. Physical Characteristics and Soil Density

Table 2 shows the results of testing the physical properties of the expansive soil (clay + Bentonite) mixed with 5% and 15% fly ash. Figure 3 depicts the results of the Scanning Electron Microscopy (SEM) test, which included photos of the soil microstructure, while Figure 4 depicts the results of the static compaction test using the standard Proctor method.

*Figure 3.* Microphotograph of soil: a) Fly ash treated soil; b) untreated soil
Compaction of clay (expansive), mixed clay with 5% and 15% fly ash with standard Proctor produces compaction curves like the one shown in Figure 4, which shows the relationship between water content and the dry volume or density of the soil. The compaction process is designed to achieve a maximum dry density with the least amount of moisture. The dry density of the expansive clay with 5% fly ash was 1.3 g/cc at the optimum moisture content of 26.8%, while the dry density of the expansive clay with 15% fly ash was 1.32 g/cc at the optimum water content of 23.7%. The addition of FA above 15% increased the dry density of the soil while decreasing the optimum water content. The condition is influenced by the chemical composition of fly ash and CaO hydration events, resulting in a decrease in water content and an increase in dry density.

The physical and mechanical properties of the soil are affected by compaction moisture content [28], [29]. Figure 4 depicts compacted clay's physical characteristics, including its composition or micro-macro structure, plasticity, and density. At the same time, its shear strength and permeability properties can express its mechanical characteristics.

Figure 5 depicts the relationship between the density level, volume change, and negative pore pressure (suction) of the soil. The density and volume of the large pores decrease, causing the void ratio to rise when the water content exceeds the optimum level. At the same moisture content, treated 15% fly ash is smaller than untreated 5% fly ash and smaller than the original soil. The soil becomes denser with the addition of 15% fly ash, resulting in a smaller pore volume and a decrease in pore number (Figure 5A). Furthermore, the negative pore-water pressure decreases (Figure 5B). When fly ash was mixed with CaO, the chemical composition of the fly ash, particularly alumina and active silica, influenced the suction change.

Figures 5C and 5D show that the expansive soil curve has a linear shape with the same slope. The curve shape is linear for 5% fly ash with a slope of 56° to a degree of saturation ($S_r$) of 70%; above 70%, the slope changes to 25°. Meanwhile, the curve is linear for a 15% FA mixture with a slope of 60° and a saturation degree of 65%. The slope changed to 23° when the degree of saturation exceeded 65%, owing to the addition of fly ash at the same water content, which increased the degree of saturation. Furthermore, the addition of 15% FA resulted in higher pore water pressure due to the lower water content (Figure 5E).

Natural clay has a maximum dry density of 1.2001 g/cc at an optimum moisture content of 28% and a suction value of 4500 kPa [7], whereas expansive soil mixed with 5% FA has a maximum dry density of 1.3 g/cc at an optimum moisture content of 28% and a suction value of 15,615.47 kPa. It also has a 15% FA of 1.32 g/cc at 23.7% optimum water content and suction of 1046.08 kPa. As a result, the addition of 15% FA results in a higher maximum density and a higher negative pore water pressure but a lower optimum water content than the addition of 5% FA (Figure 5E and 5F).
Figure 5. Relationship of water content (w), void ratio (e), degree of saturation (Sr), and stress
3.2. Change in Compressive Strength (\(qu\)) of 5% FA Treated Soil due to Repeated Drying-Wetting Cycle

Figure 6 presents the changes in compressive strength (\(qu\)) of expansive soil mixed with 5% FA as the water content decreased due to repeated drying (drying path).

However, as shown in Figure 6, the compressive strength of the soil increases with each cycle; in drier soil conditions (water content less than 40%), the compressive strength of the soil increases significantly. The soil compressive strength decreased significantly and gradually decreased after four drying cycles because of the repeated drying cycles. Several previous studies using different methods and soil types concluded that the decrease in soil compressive strength after the fourth cycle is negligible. Previous research has discovered that as the number of drying cycles increases, the bleach concentration decreases [7], [11], [12], [23]. The increased soil saturation (\(Sr\)) due to the cycle's repetition caused this decrease.

Furthermore, Figure 7 represents the change in compressive strength of the expansive soil + 5% FA due to repeated wetting cycles (wetting path). Following Figure 7, the decrease in compressive strength caused by repeated wetting cycles is not too significant, especially at water content levels above 40%. When the water content is less than 30%, the compressive strength of the soil is lower than during the drying process. The soil's degree of saturation (\(Sr\)) changes, then the soil compressive strength decreases as the number of cycles increases. The soil void ratio decreases, causing soil density to increase and the soil strength to increase. Previous research has also discovered that higher density produces more clay particles with parallel and parallel orientations under certain water content conditions, resulting in more excellent soil structure dispersion [30], [31].

Figure 6. Compressive strength of 5% FA treated soil on drying path
3.3. Change in Compressive Strength ($q_u$) of 15% FA Treated Soil due to Repeated Drying-wetting Cycle

Figures 8 and 9 represent the change in compressive strength of the expansive soil with the addition of 15% FA due to repeated drying and wetting cycles.

Based on the data, the expansive soil with 15% FA has higher compressive strength and a smaller particle structure than the mixed soil with 5% FA. With its lower water content and smaller pore volume, this soil is more stable. This condition is thought to be caused by the chemical composition of fly ash, which functions to reduce water content and improve soil physical properties due to CaO hydration, where the mixed CaO content of 15% FA exceeds 5% FA.
3.4. The Compressive Strength ($q_u$) and Stress-Strain Modulus ($E_i$) Changes to the Number of Wetting Paths of 25%, 50%, and 100%

The relationship between the compressive strength ($q_u$) and the stress-strain modulus on the number of cycles on the Proctor specimen with 25% wetting shows in Figure 10 and 11.

Based on Figs. 10 and 11, it is clear that the expansive clay soil experienced a 26% decrease in soil compressive strength ($q_u$) and a 2% decrease in soil stress-strain modulus ($E_i$) in 1-2 cycles, a 28% decrease of compressive strength, and a 19% decrease of $E_i$ in 2-4 cycles, while no visible compressive strength change at 4-6 cycles.

Furthermore, a 5% FA mixed soil exhibits minimal compressive strength and stress-strain modulus for 2-4 times cycles. The compressive strength ($q_u$) decreases by 47%, and $E_i$ decreases by 25%. The number of cycles is between 4-6 times, and the compressive strength value is close to constant. Meanwhile, for mixed soil 15% FA, the decrease in strength for 1-2 times cycles is 14.5%, in cycles of 2-4 times, the decrease in compressive strength ($q_u$) is 38% and $E_i$ is 28%, while for 4-6 times cycles the $q_u$ and $E_i$ are deficient.
The changes of $q_u$ and $E_i$ during the 50% wetting cycle represents in Figure 12. Based on the figures, it is clear that the increase of compressive strength and stress-strain modulus in cycles of 1-6 times is very small or insignificant.

Meanwhile, the 5% FA mixture reduced compressive strength by 18% and stress-strain modulus by 42% in 1-2 cycles, but the $q_u$ and $E_i$ change was very small or insignificant in 2-6 cycles. Furthermore, in cycles 1-2, the 15% FA compressive strength decreased by 18%, and $E_i$ decreased by 42%, and in cycles 2-4, it decreased by 30%, and the stress-strain modulus was 17%, but the change was minimal after cycle 4.

The compressive strength ($q_u$) and stress-strain modulus ($E_i$) change to 100% wetting on compacted untreated and treated with 5% and 15% fly ash are shown in Figure 13. The figure shows that the soil $q_u$ and $E_i$ did not change during cycles 1-6. Compressive strength and stress-strain modulus decreased by 33% in 1-2 cycles, 30% in 2-4 cycles, and 60% in 4-6 cycles, respectively, with compressive strength decreasing insignificantly in 4-6 cycles. Meanwhile, after 1-2 cycles, the mixed soil was 15% FA, the compressive strength was 41% lower, and the stress-strain modulus was 42% lower. The compressive strength of the soil should not decrease as the void ratio and dry density decrease [32], [33]. It was thought to be because water trapped in soil ped is difficult to escape, increasing the degree of saturation and decreasing compressive strength ($q_u$) and stress-strain modulus. Furthermore, after 2-4 cycles, the compressive strength and stress-strain modulus increase as the void ratio decreases and the soil strain decreases, making water entry into the soil grains more difficult [7], [12], [23].
Conclusions

Laboratory tests on the compressive strength changes of fly ash stabilized expansive soil were carried out, and the results are summarized below. The compressive strength characteristics of the soil are significantly influenced by repeated drying and wetting cycles. The compressive strength of the soil appears to decrease as the drying-wetting cycle is repeated, although the soil density increases and the void ratio decreases. When soil is compacted, the saturation level rises, and the void ratio falls, resulting in this situation. The soil compaction that occurs during the wetting-drying process does not allow the water to escape completely, so much water is trapped in the soil ped and reduces the compressive strength of the soil. Compressive strength ($q_u$) and stress-strain modulus ($E_i$) tend to decrease in the first 1-4 cycles, and changes cease to be significant after the fourth cycle. As a result, the proposed method effectively reduces the decrease in expansive soil strength caused by environmental changes (wetting-drying), contributing significantly to material development to reduce structural damage caused by soil swelling-shrinkage.
