Two-dimensional (2D) van der Waals ferromagnetic materials are emerging as promising candidates for applications in ultra-compact spintronic nanodevices, nanosensors, and information storage. Our recent discovery of the strong room temperature ferromagnetism in single layers of VSe₂ grown on graphite or MoS₂ substrate has opened new opportunities to explore these ultrathin magnets for such applications. In this paper, we present a new type of magnetic sensor that utilizes the single layer VSe₂ film as a highly sensitive magnetic core. The sensor relies in changes in resonance frequency of the LC circuit composed of a soft ferromagnetic microwire coil that contains the ferromagnetic VSe₂ film subject to applied DC magnetic fields. The sensitivity of the sensor reaches an extremely high value of 16×10⁶ Hz/Oe, making it an excellent candidate for a wide range of magnetic sensing applications.

Since intrinsic long-range ferromagnetic order was realized in 2017 with bulk exfoliated monolayers of Cr$_2$Ge$_2$Te$_6$ and CrI$_3$,\textsuperscript{1,2} the potential of two-dimensional (2D) van der Waals magnets has excited the scientific community.\textsuperscript{3-11} While these 2D magnets have demonstrated their usefulness in magnetoelectric devices, their technological applications are restricted to low temperatures ($< 100$ K).\textsuperscript{6-10} In contrast, recent discoveries of the room temperature (RT) ferromagnetism in transition metal dichalcogenide (TMD) monolayers of VSe$_2$ and MnSe$_2$ grown by van der Waals epitaxy on various substrates (graphite, MoS$_2$, GaSe) may enable applications at ambient temperature.\textsuperscript{3,4,10}

In this paper, we present a new type of magnetic sensor that integrates a single layer VSe$_2$ film within a Co-rich microwire-based coil. We note that induction coil sensors have been widely used due to the simplicity of their construction and a well known transfer function.\textsuperscript{12} It is established that the sensitivity of an induction coil is limited by the number of windings; the greater the number of turns the higher the sensitivity. This quickly becomes a problem for modern applications where it is desirable to limit the size of sensors. Adding a soft ferromagnetic core with high relative permeability can largely increase the sensitivity of a coil, and hence allow for smaller sensor sizes.\textsuperscript{13} A similar working principle has recently been used in the design of MMC-LC resonator sensors, but cobalt-rich magnetic microwires are used instead of non-magnetic conductors such as copper.\textsuperscript{14} The working principle of the sensor reported in this paper is fundamentally different than that of a conventional induction coil sensor. It relies on the changes in resonance frequency caused by external magnetic fields, instead of simply measuring the induction of the coil. It is also different from the MMC-LC resonator sensor\textsuperscript{14} that relies in changes in impedance of the microwire caused by external magnetic fields.
A simple model for a coil sensor is a lumped element representation of a non-ideal inductor. Winding cylindrical conductors close to each other will introduce parasitic elements $R_{par}$ and $C_{par}$, such that the non-ideal inductor can be represented as a series combination of an ideal inductor $L$ and $R_{par}$, in parallel with $C_{par}$.\textsuperscript{15,16,17} The impedance of the coil $Z_{coil}$ can then be written as

$$Z_{coil} = (Z_{R_{par}} + Z_{L}) \parallel Z_{C_{par}}$$ \hfill (1)

$$Z_{coil} = \frac{1}{\frac{1}{R_{par} + j\omega L} + \frac{1}{j\omega C_{par}}}$$ \hfill (2)

$$Z_{coil} = \frac{R_{par} + j\omega[L(1-\omega^2LC_{par}) - C_{par}R_{par}^2]}{(1-\omega^2LC_{par})^2 + (\omega C_{par}R_{par})^2},$$ \hfill (3)

where $\omega$ is the angular frequency, and $j$ is the imaginary unit. Resonance will occur when the inductive reactance ($X_L$) and the capacitive reactance ($X_C$) are equal in magnitude but differ in phase by 180 degrees. At this point very little current flows through the wire, the impedance $Z_{coil}$ becomes very large and self-resonance is achieved.\textsuperscript{18,19} The resonance frequency is given by

$$f_0 = \frac{\sqrt{1 - (R_{par}^2C_{par}/L)}}{2\pi\sqrt{L}\sqrt{C_{par}}},$$ \hfill (4)

where $f_0$ is the resonance frequency. We expect a self-resonant behavior in the MMC as well, but the resonance frequency will be different than that of the inductor since the wire is now a magnetic material. We must also consider the effects of a ferromagnetic core on the sensor. The core will modify the relative permeability in the space within the coil, and this will in turn change the flux through the coil and hence affect the inductance. Since the permeability is field dependent, an external magnetic field will modify the permeability of the core and the resonance
frequency with it. The sensitivity of the sensor is defined as the rate of change of the resonance frequency with respect to the external DC magnetic field,

\[ Sensitivity = \frac{df_0}{dH} \]  

(5)

The \( Q \) factor is also calculated by measuring the bandwidth, BW, and the resonance frequency using the following relation,

\[ Q = \frac{f_0}{BW} \]  

(6)

To make the magnetic sensor, a \( \text{Co}_{69.25}\text{Fe}_{4.25}\text{Si}_{13}\text{B}_{12.5}\text{Nb}_{1} \) wire (diameter, \( \sim 60 \mu\text{m} \)) was wound into a 15-turn, 10 mm long coil with a 5 mm internal diameter. The fabrication details and material characterization of the microwire can be found elsewhere.\(^{20,21}\) Monolayer VSe\(_2\) was used as the core of the coil. The single layer films of VSe\(_2\) were grown on graphite (HOPG) and single crystal MoS\(_2\) by molecular beam epitaxy (MBE); the details of which have been reported in our previous work.\(^3\) Since both monolayer VSe\(_2\) samples grown on MoS\(_2\) and HOPG show similar magnetic and sensing properties, in this paper we only report on the properties of monolayer VSe\(_2\) grown on MoS\(_2\). Figure 1(a) shows a typical scanning tunnel microscopy (STM) image of the VSe\(_2\) film. It can be seen that the single layer of VSe\(_2\) was epitaxially grown on the MoS\(_2\) substrate. The magnetization versus magnetic field (\( M-H \)) curves, measured by a vibrating sample magnetometer (VSM) on VSe\(_2\) grown on both HOPG and MoS\(_2\), show a soft ferromagnetic characteristic (small coercive field, small remanent magnetization, and high saturation magnetization) of the single layer VSe\(_2\) film at room temperature (Fig. 1(b)), which is desirable for its use as the core of the sensor that itself operates at room temperature. The core was \( \sim 14 \) mm long and \( \sim 0.4 \) mm wide, allowing us to insert and remove the core with ease. The sensor was mounted on a test fixture made of a dielectric material on top of a copper ground
plane; SMA connector ports were soldered to the ground plane on two ends and the two leads of the inductor were soldered to the center pin of each connector.

One port reflection measurements were performed with an HP 4191A impedance analyzer over the frequency range 1 – 200 MHz. A simple short-open-load (SOL) calibration was made. The test fixture was connected to the impedance analyzer through a coaxial cable, and it was terminated with a 50 ohm cap. The effects of the cable were removed by the calibration. The impedance ($Z$), resistance ($R$), and reactance ($X$) are calculated from the reflection measurement. An external DC magnetic field was generated by a Helmholtz coil. A diagram of the setup is shown in Fig. 1(c,d). The external field was applied transverse to the coil axis as the frequency was swept. A frequency sweep was performed for every value of the field which was swept from -30 to 30 Oe in steps of 1 Oe.

A set of measurements is performed to characterize the sensor; the resonance frequency is found for every value of the field. Resonance is determined by the zero crossing of the reactance. To see the effects of the monolayer core we show in Fig. 2(a) the reactance of the coil with and without the monolayer core at zero field. The presence of the monolayer shifts the resonance frequency of the sensor by a few megahertz. We then applied the external field and observed how the reactance curve is shifted along with the corresponding resonance frequency as shown in Fig. 2(b), for the coil with the monolayer in its core. The reactance of the coil being proportional to the inductance changes drastically with frequency and applied field, as well as the resonance frequency (see Fig. 2(c)).

The resonance frequency is determined for every value of the field. Figure 3(a) shows the change in resonance frequency as a function of applied field. Unique values of the resonance frequency exist for fields smaller than 5 Oe. At higher fields, the magnetic wire saturates, and $f_0$
changes very slowly, rending the sensor inoperable. A fit of the right branch of the $f_0$ plot is shown in Fig. 3(b) as well as the sensitivity of the sensor. Values as large as $16 \times 10^6$ Hz/Oe are achieved for the sensitivity. The massive value of the sensitivity shows that the present sensor can be used to accurately determine the magnitude of small magnetic fields as well as subtle variations in them. This brings forth a wide range of applications such as bio-detection, where magnetic nanoparticles are used as bio-markers for pathogen detection and quantifying low particle concentrations is neccessary.\textsuperscript{22} Finally, we have determined the Q factor of the sensor at different values of external DC magnetic field, as shown in Fig. 4. We have found that for very small fields, smaller than 1 Oe, the Q factor is 0.6; as the field increases it reaches a minimum value of 0.36 at 3 Oe. Most of the losses are associated with the magnetic wire itself; the core slightly decreases the Q factor by less than 0.1. This is consistent with the soft ferromagnetic characteristic of monolayer VSe$_2$ (Fig. 1(b)), which predicts minimal magnetic losses.

In summary, a highly sensitive magnetic field sensor was built using a magnetic microwire coil as the sensing element with a single layer VSe$_2$ film as the core. Sensitivity as large as $16 \times 10^6$ Hz/Oe for very small fields was obtained. We successfully implemented VSe$_2$ monolayers in room temperature magnetic field sensors. Furthermore, core losses were shown to be minimal which is desirable for sensor design.
