Abstract

In this work a theory is developed for unifying large classes of nonlinear discrete-time dynamical systems obeying a superposition of a weighted maximum or minimum type. The state vectors and input-output signals evolve on nonlinear spaces which we call complete weighted lattices and include as special cases the nonlinear vector spaces of minimax algebra. Their algebraic structure has a polygonal geometry. Some of the special cases unified include max-plus, max-product, and probabilistic dynamical systems. We study problems of representation in state and input-output spaces using lattice monotone operators, state and output responses using nonlinear convolutions, solving nonlinear matrix equations using lattice adjunctions, stability and controllability. We outline applications in state-space modeling of nonlinear filtering; dynamic programming (Viterbi algorithm) and shortest paths (distance maps); fuzzy Markov chains; and tracking audio-visual salient events in multimodal information streams using generalized hidden Markov models with control inputs.

1 Introduction

Linear dynamical systems \[11, 13, 27\] can be described in discrete-time by the state space equations

\[
\begin{align*}
  x(t) &= Ax(t-1) + Bu(t) \\
  y(t) &= Cx(t) + Du(t)
\end{align*}
\]

where \(t \in \mathbb{Z}\) shall denote a discrete time index, \(x(t)\) is an evolving state vector, \(u(t)\) is the input signal (scalar or vector), and \(y(t)\) is an output signal (scalar or vector). \(A, B, C, D\) are appropriately sized matrices and all the matrix-vector products are defined in the standard linear way. Linear systems have proven useful for a plethora of problems in communications, control and signal processing. The strongest motivation for using linear systems as models has been the great familiarity of all sciences with linear mathematics, e.g. linear algebra, linear vector spaces, and linear differential equations, as well as the availability of computational tools and algorithms to solve problems with linear systems.

However, in the 1980s and 1990s, several broad classes of nonlinear systems were developed whose state-space dynamics can be described by equations whose structure resembles \([11]\) but has nonlinear operations. These were motivated by a broad spectrum of applications, such as scheduling, operations research, dynamic programming, graph shortest paths, image analysis, and non-Gaussian estimation, for which nonlinear systems were more appropriate. These nonlinearities involve two major elements: 1) a nonlinear superposition of vectors/matrices via pointwise maximum (\(\lor\)) or minimum (\(\land\)) which plays the role of a generalized ‘addition’, and 2) a binary operation \(\ast\) among scalars that plays the role of a generalized ‘multiplication’. Thus, with the above generalized ‘addition’ and ‘multiplication’, the set of scalars has a conceptually similar algebraic structure as the field of reals with standard addition and multiplication underlying the linear vector spaces over which linear systems act. This alternative algebraic structure (with operations \(\lor, \ast\)) is minimally a semiring. Examples of ‘multiplication’ include the sum and the product, but \(\ast\) may also be only a semigroup operation. The resulting algebras include 1) the max-plus algebra \((\mathbb{R} \cup \{-\infty\}, \max, +)\) used in scheduling and operations research \([13]\), discrete event systems (DES) \([16, 2, 15]\), automated manufacturing \([28, 19]\), max-plus control \([16, 22, 14]\), and neural nets with max-plus combinations of inputs \([43]\); 2) the min-plus algebra or else known as tropical semiring \((\mathbb{R} \cup \{+\infty\}, \min, +)\) used in shortest paths on networks \([18]\) and in speech recognition and natural language processing \([39, 25]\); this is a logarithmic version of 3) the max-product probability semiring used for inference with belief propagation in graphical models \([11, 7]\); 4) the fuzzy logic or probability semiring \(([0, 1], \lor, T)\) with statistical \(T\)-norms used in probabilistic automata and fuzzy neural nets \([30, 26]\), fuzzy image processing and dynamical systems \([8, 38]\), and fuzzy Markov chains \([1]\). Further, in multimodal processing for cognition modeling, several psychophysical and computational experiments indicate that the superposition of sensory signals or cognitive states seems to be better modeled using max or min rules, possibly weighted. Such an example is the work \([20]\) on attention-based multimodal video summarization where a (possibly weighted)
min/max fusion of features from the audio and visual signal channels and of salient events from various modalities seems to outperform linear fusion schemes. Tracking of these salient events was recently modeled in [36] using a max-product dynamical system. Finally, the problem of bridging the semantic gap in multimedia requires integration of continuous sensory modalities (like audio and/or vision) with discrete language symbols and semantics extracted from text. Similarly, in control and robotics there are efforts to develop hybrid systems that can model interactions between heterogeneous information streams like continuous inputs and symbolic strings, e.g. motion control with language-driven variables [12]. In both of these applications we need models where the computations among modalities/states can handle both real numbers and Boolean-like variables; this is possible using max/min rules.

Motivated by the above applications, in this work we develop a theory and some tools to unify the representation and analysis of nonlinear systems whose dynamics evolve based on the following max-⋆ model

\[
\begin{align*}
  x(t) &= A(t) \boxtimes x(t-1) \lor B(t) \boxtimes u(t) \\
  y(t) &= C(t) \boxtimes x(t) \lor D(t) \boxtimes u(t)
\end{align*}
\]

where \( x = [x_1, x_2, ..., x_n]^T \in \mathcal{K}^n \) is a \( n \)-dimensional state vector with elements from the scalars’ set \( \mathcal{K} \), which will generally be a subset of the extended reals \( \mathbb{R} = \mathbb{R} \cup \{-\infty, \infty\} \). The linear matrix product in (1), which is based on a sum of products, is replaced in (2) by a nonlinear matrix product \( (\boxtimes) \) based on a max of \( \star \) operations, where \( \star \) shall denote our general scalar operation discussed in Sec. 3.1. The max-⋆ ‘multiplication’ of a matrix \( A = [a_{ij}] \in \mathcal{K}^{m \times n} \) with a vector \( x = [x_i] \in \mathcal{K}^n \) yields a vector \( b = [b_i] \in \mathcal{K}^m \) defined by:

\[
A \boxtimes x = b, \quad b_i = \bigvee_{j=1}^n a_{ij} \star x_j
\]

Further, the pointwise ‘addition’ of vectors (and possibly matrices) of same size in (1) is replaced in (2) by their pointwise \( \lor \):

\[
\begin{align*}
  x \lor y &= [x_1 \lor y_1, \ldots, x_n \lor y_n]^T \\
  A \lor B &= [a_{ij} \lor b_{ij}]
\end{align*}
\]

A max-plus \( 2 \times 2 \) example of (3) is

\[
\begin{bmatrix}
  4 & -1 \\
  2 & -\infty
\end{bmatrix} \boxtimes
\begin{bmatrix}
  x \\
  y
\end{bmatrix} =
\begin{bmatrix}
  3 \\
  1
\end{bmatrix}, \quad \max(x + 4, y - 1) = 3
\]

with solution \( x = -1 \) and \( y \leq 4 \).

By replacing maximum \( (\lor) \) with minimum \( (\land) \) and the \( \star \) operation with a dual operation \( \star' \) we obtain a dual model that describes the state-space dynamics of \( \text{min-}\star' \) systems:

\[
\begin{align*}
  x(t) &= A(t) \boxtimes' x(t-1) \land B(t) \boxtimes' u(t) \\
  y(t) &= C(t) \boxtimes' x(t) \land D(t) \boxtimes' u(t)
\end{align*}
\]

where the min-⋆' matrix-vector ‘multiplication’ is defined by:

\[
A \boxtimes' x = b, \quad b_i = \bigwedge_{j=1}^n a_{ij} \star' x_j
\]

The state equations (2) and (6) have time-varying coefficients. For constant matrices \( A, B, C, D \), we obtain the constant-coefficient case.

By specifying the scalar ‘multiplication’ \( \star \) and its dual \( \star' \), we obtain a large variety of classes of nonlinear dynamical systems that are described by the above unified algebraic models of the max or min type. The most well-known special case is \( \star = + \), the principal interpretation of minimax algebra, which has been extensively studied in scheduling [18], DES [16, 2], and max-plus control.
In typical applications of DES in automated manufacturing, the states $x_i(t)$ represent starting times of the $t$-th cycle of machine $i$, the input $u$ represents availability times of parts, $y$ represents completion times, and the elements of $A, B, C, D$ represent activity durations. The homogeneous state dynamics of (2) are modeled by max-plus recursive equations:

$$x_i(t) = \max_{1 \leq j \leq n} a_{ij} + x_j(t-1), \quad i = 1, \ldots, n \tag{8}$$

Another (less frequently related to minimax algebra) special case is $\star = \times$, which is used in communications (e.g. Viterbi algorithm), in probabilistic networks [41, 7] as the max-product belief propagation, and in speech recognition and language processing [39, 25]. But both its max-product algebra and its general dynamics with control inputs have not been studied. Other cases are much less studied or relatively unknown.

Our theoretical analysis is based on a relatively new type of nonlinear space we have developed in recent work [35] and further extend herein, which we call complete weighted lattice (CWL). This combines two vector or signal generalized ‘additions’ of the supremum ($\vee$) or the infimum ($\wedge$) type and two generalized scalar multiplications, $\star$ and its dual $\star'$, which distribute over $\vee$ and $\wedge$ respectively. The axioms of CWLs bear a remarkable similarity with those of linear spaces as noted in [35], the major difference being the lack of inverses for the sup/inf operations and sometimes for the $\star$ operation too. The present work focuses on analyzing max/min dynamical systems using CWLs, whose advantages over the minimax algebra [18], which has been so far the main algebraic framework for DES and max-plus control, include the following:

1) CWLs can apply both to finite- and infinite-dimensional spaces whereas minimax algebra is a matrix algebra on finite-dimensional vector spaces.

2) Their theoretical foundation contains a built-in duality which allows co-existence of the max-$\star$ and its dual min-$\star'$ algebra.

3) We believe that lattice theory [6] offers a conceptually elegant and more compact way to express the combined rich algebraic structure instead of viewing it as two idempotent semirings of minimax algebra.

4) Lattice monotone operators of the dilation ($\delta$) or erosion ($\varepsilon$) type can be defined, as done in morphological image analysis [15, 23], which play the role of ‘linear operators’ on CWLs and can represent systems obeying a max-$\star$ or a min-$\star'$ superposition respectively. Such operators can represent both state vector transformations by matrix-vector generalized products of the max-$\star$ or min-$\star'$ type, as in (3) and (7), as well as input-output signal mappings in the form of nonlinear convolutions of two signals $f$ and $g$: sup-$\star$ convolution

$$ (f \bigcirc g)(t) \triangleq \bigvee_k f(k) \star g(t-k), \tag{9} $$

or inf-$\star'$ convolution

$$ (f \bigcirc' g)(t) \triangleq \bigwedge_k f(k) \star' g(t-k) \tag{10} $$

The only well-known special case $\star = +$ is called supremal or infimal convolution in convex analysis and optimization [41, 44, 31] as well as weighted (Minkowski) signal dilation or erosion in morphological image analysis and vision [35, 23, 34]. Other cases are much less studied or relatively unknown.

5) Modeling the information flow in these dynamical systems via the above lattice operators is greatly enabled by the concept of adjunction, which is a pair $(\varepsilon, \delta)$ of erosion and dilation operators forming a type of duality expressed by the following

$$ \delta(x) \leq y \iff x \leq \varepsilon(y) \tag{11} $$

for any vectors or signals $x, y$.

From a geometrical viewpoint, we may call the CWLs polygonal spaces because of the geometric shape of the corner-forming piecewise-straight lines $y = \max(a + x, b)$ or $y = \max(ax, b)$ and their
New Contributions in our work:
(i) Unify all types of max-$\star$ and min-$\star'$ systems under a common theoretical framework of complete weighted lattices (CWLs). Further, while previous work focused only on the max-plus or min-plus formalism separately, we join both using CWLs and generalize them by replacing $+$ with any commutative operation $\star$ that distributes over $\lor/\land$.

(ii) Analyze their dynamics both in state space using a CWL matrix-vector algebra as well as in the input-output signal space using sup/inf-$\star$ convolutions, represented via lattice monotone operators in adjunction pairs.

(iii) Enable and simplify the analysis and proofs of various results in system representation using lattice adjunctions. Further, use the latter to generate lattice projections that provide optimal solutions for max-$\star$ equations $A\star x = b$.

(iv) Study causality, stability, and controllability of max-$\star$ and min-$\star'$ systems and link stability with spectral analysis in max-$\star$ algebra and controllability with lattice projections.

(v) Advance the study of special cases employed in many application areas: a) Nonlinear systems represented by max/min-sum ($\star = +$) difference equations, as applied to geometric filtering and shortest path computation. State equations and stability analysis of recursive nonlinear filters. b) Max-product systems ($\star = \times$) that extend the Viterbi algorithm of hidden Markov models to cases with control inputs and can model cognitive processes related to audio-visual attention. c) Probabilistic automata and fuzzy Markov chains governed by max/min rules and with arithmetic based on triangular norms.

Notation: We think that the currently used notation in max-plus algebra of $\oplus$ and $\otimes$ to denote the maximum $\lor$ (‘addition’) and the $\star$ (‘multiplication’) respectively obscures the lattice operations; in contrast our proposed notation is simpler and more realistic since it uses the well-established symbols $\lor, \land$ for sup/inf operations and does not bias the arbitrary scalar binary operation $\star$ with the symbol $\otimes$. Further, we use roman letters for functions, signals and their arguments and greek letters for operators. Also, boldface roman letters for vectors (lowcase) and matrices (capital). If $M = [m_{ij}]$ is a matrix, its $(i,j)$-th element is also denoted as $\{M\}_{ij} = m_{ij}$. Similarly, if $x = [x_i]$ is a vector, its $i$-th element is denoted as $\{x\}_i$ or simply $x_i$.

2 Lattices and Monotone Operators

Most of the background material in this section follows [6], [45], [24], [23] and [35].
2.1 Lattices

A partially-ordered set, briefly poset \((\mathcal{P}, \leq)\), is a set \(\mathcal{P}\) with a binary relation \(\leq\) that is a partial ordering, i.e. is reflexive, antisymmetric and transitive. If, in addition, for any two elements \(X, Y \in \mathcal{P}\) we have either \(X \leq Y\) or \(Y \leq X\), then \(\mathcal{P}\) is called a chain. To every partial ordering \(\leq\) there corresponds a dual partial ordering \(\leq'\) defined by “\(X \leq' Y\) iff \(X \geq Y\)”. Let \(\mathcal{S}\) be a subset of \((\mathcal{P}, \leq)\); an upper bound of \(\mathcal{S}\) is an element \(B \in \mathcal{P}\) such that \(X \leq B\) for all \(X \in \mathcal{S}\). The least upper bound of \(\mathcal{S}\) is called its supremum and denoted by \(\sup \mathcal{S}\) or \(\bigvee \mathcal{S}\). By duality, we define the greatest lower bound of \(\mathcal{S}\), called its infimum and denoted by \(\inf \mathcal{S}\) or \(\bigwedge \mathcal{S}\). If the supremum (resp. infimum) of \(\mathcal{S}\) belongs to \(\mathcal{S}\), then it is called the the greatest element or maximum (resp. least element or minimum) of \(\mathcal{S}\). An element \(M\) of \(\mathcal{S}\) is called maximal (resp. minimal) if there is no other element in \(\mathcal{S}\) that is greater (resp. smaller) than \(M\).

A lattice is a poset \((\mathcal{L}, \leq)\) any two of whose elements have a supremum, denoted by \(X \lor Y\), and an infimum, denoted by \(X \land Y\). We often denote the lattice structure by \((\mathcal{L}, \lor, \land)\). A lattice is \(\mathcal{L}\) is complete if each of its subsets (finite or infinite) has a supremum and an infimum in \(\mathcal{L}\). Any nonempty complete lattice is universally bounded because it contains its supremum \(\top = \lor \mathcal{L}\) and infimum \(\bot = \land \mathcal{L}\) which are its greatest and least elements, respectively. In any lattice \(\mathcal{L}\), by replacing the partial ordering with its dual and by interchanging the roles of the supremum and infimum we obtain a dual lattice \(\mathcal{L}'\). Duality principle: to every definition, property and statement that applies to \(\mathcal{L}\) there corresponds a dual one that applies to \(\mathcal{L}'\) by interchanging \(\leq\) with \(\leq'\) and \(\lor\) with \(\land\). A bijection between two lattices \(\mathcal{L}\) and \(\mathcal{M}\) is called an isomorphism (resp. dual isomorphism) if it preserves (resp. reverses) suprema and infima. If \(\mathcal{L} = \mathcal{M}\), a (dual-) isomorphism on \(\mathcal{L}\) is called (dual-) automorphism.

The lattice operations satisfy many properties, as summarized in Table 1. Conversely, a set \(\mathcal{L}\) equipped with two binary operations \(\lor\) and \(\land\) that satisfy properties \((L1,L1')\)--\((L5,L5')\) is a lattice whose supremum is \(\lor\), the infimum is \(\land\), and partial ordering \(\leq\) is given by \((L6)\). A lattice \((\mathcal{L}, \lor, \land)\) contains two weaker substructures: a sup-semilattice \((\mathcal{L}, \lor)\) that satisfies properties \((L1--L4)\) an inf-semilattice \((\mathcal{L}, \land)\) that satisfies properties \((L5'--L4')\).

The additional properties \((L7,L7')\) and \((L8,L8')\) in Table 1 hold only if the lattice contains a least and a greatest element, respectively. A lattice \(\mathcal{L}\) is called distributive if it satisfies properties \((L9,L9)\); if these also hold over infinite set collections, then the lattice is called infinitely distributive. The rest of the properties of Table 1, labeled as “WL#”, refer to a richer algebra defined as ‘weighted lattices’ in Section 3.2.

Lattice Examples: (a) Any chain is an infinitely distributive lattice. Thus, the chain \((\mathbb{R}, \leq)\) of real numbers equipped with the natural order \(\leq\) is a lattice, but not complete. The set of extended real numbers \(\mathbb{R} = \mathbb{R} \cup \{-\infty, +\infty\}\) is a complete lattice.

(b) The power set \(\mathcal{P}(E) = \{X : X \subseteq E\}\) of an arbitrary set \(E\) equipped with the partial order of set inclusion is an infinitely distributive lattice under the supremum and infimum induced by set inclusion which are the set union and intersection, respectively.

(c) In a lattice \(\mathcal{L}\) with universal bounds \(\bot\) and \(\top\), an element \(X \in \mathcal{L}\) is said to have a complement \(X^c \in \mathcal{L}\) if \(X \lor X^c = \top\) and \(X \land X^c = \bot\). If all the elements of \(\mathcal{L}\) have complements, then \(\mathcal{L}\) is called complemented. Any complemented and distributive lattice \(\mathcal{B}\) is called a Boolean lattice.

(d) Let \(\mathcal{L}^E = \text{Fun}(E, \mathcal{L})\) denote the set of all functions \(f : E \to \mathcal{L}\). If \(\leq\) is the partial ordering of \(\mathcal{L}\), we can equip the function space \(\mathcal{L}^E\) with the pointwise partial ordering \(f \leq g\), which means \(f(x) \leq g(x)\) \(\forall x \in E\), the pointwise supremum \(\bigvee_i f_i(x) = \bigvee_i f_i(x)\), and pointwise infimum \(\bigwedge_i f_i(x) = \bigwedge_i f_i(x)\). Then, \((\mathcal{L}^E, \lor, \land)\) becomes a function lattice, which retains possible properties of \(\mathcal{L}\) of being complete, or (infinitely) distributive, or Boolean.

2.2 Operators on Lattices

Let \(\mathcal{O}(\mathcal{L})\) be the set of all operators on a complete lattice \(\mathcal{L}\), i.e., mappings from \(\mathcal{L}\) to itself. Given two such operators \(\psi\) and \(\phi\) we can define a partial ordering between them \((\phi \leq \psi)\), their supremum \((\psi \lor \phi)\) and infimum \((\psi \land \phi)\) in a pointwise way, as done in Example 2.1(d). This makes \(\mathcal{O}(\mathcal{L})\) a
complete function lattice which inherits many of the possible properties of $\mathcal{L}$. Further, we define the composition of two operators as an operator product: $\psi \phi(X) \triangleq \psi(\phi(X))$; special cases are the operator powers $\psi^n = \psi \psi^{n-1}$. Some useful types and properties of lattice operators $\psi$ include the following: (i) identity: $\text{id}(X) = X \forall X \in \mathcal{L}$. (ii) extensive: $\psi \geq \text{id}$. (iii) antiextensive: $\psi \leq \text{id}$. (iv) idempotent: $\psi^2 = \psi$. (v) involution: $\psi^2 = \text{id}$.

### 2.2.1 Monotone Operators

Of great interest are the monotone operators, whose collections form sublattices of $\mathcal{O}(\mathcal{L})$. They come in three basic kinds according to which of the following lattice structures they preserve (or map to its dual): (i) partial ordering, (ii) supremum, (iii) infimum.

A lattice operator $\psi$ is called increasing or isotone if it is order-preserving, i.e. $X \leq Y \implies \psi(X) \leq \psi(Y)$. A lattice operator $\psi$ is called decreasing or antitone if it is order-inverting, i.e. $X \leq Y \implies \psi(X) \geq \psi(Y)$.

Examples of increasing operators are the lattice homomorphisms which preserve suprema and infima over finite collections. If a lattice homomorphism is also a bijection, then it becomes an automorphism. A bijection $\phi$ is an automorphism if both $\phi$ and its inverse $\phi^{-1}$ are increasing.

Four types of increasing operators, fundamental for unifying systems on lattices, are the following:

- $\delta$ is dilation iff $\delta(\bigvee_i X_i) = \bigvee_i \delta(X_i)$
- $\varepsilon$ is erosion iff $\varepsilon(\bigwedge_i X_i) = \bigwedge_i \varepsilon(X_i)$
- $\alpha$ is opening iff increasing, idempotent, antitonic
- $\beta$ is closing iff increasing, idempotent, extensive

Dilation and erosion operators require arbitrary (possibly infinite) indexed collections; hence, they need complete lattices. The four above types of lattice operators were originally defined in [45, 23] as generalizations of the corresponding standard morphological image operators.

Examples of decreasing operators are the dual homomorphisms, which interchange suprema with infima. A lattice dual-automorphism is a bijection $\theta$ that interchanges suprema with infima, or equivalently iff it is a bijection and both $\theta$ and its inverse $\theta^{-1}$ are decreasing. A negation $\nu$ is a dual automorphism that is also involutive; we may write $X^\neg = \nu(X)$ for the negative of a lattice element. Given an operator $\psi$ in a lattice equipped with a negation, its corresponding dual (a.k.a. negative) operator is defined as $\psi^\neg(X) \triangleq [\psi(X^\neg)]^\neg$. For example, the most well-known negation on the set lattice $\mathcal{P}(E)$ is the complementation $\nu(X) = X^c = E \setminus X$, whereas on the function lattice $\text{Fun}(E, \mathbb{R})$ the most well-known negation is $\nu(f) = -f$.

The above definitions allow broad classes of operators on vector or signal spaces to be grouped as parallel or sequential combinations of lattice monotone operators and their common properties to be studied under the unifying lattice framework. In this work we shall find them very useful for representing the state and output responses or for approximating solutions of systems obeying a supremal or infimal superposition.

### 2.2.2 Adjunctions and Projections on Lattices

Dilations and erosions come in pairs as the following concept reveals. The pair $(\varepsilon, \delta)$ of two operators $\delta$ and $\varepsilon$ on a complete lattice $\mathcal{L}$ is called an adjunction on $\mathcal{L}$ if

$$\delta(X) \leq Y \iff X \leq \varepsilon(Y) \quad \forall X, Y \in \mathcal{L}$$

(12)

In any adjunction $(\varepsilon, \delta)$, $\varepsilon$ is called the adjoint erosion of $\delta$, whereas $\delta$ is the adjoint dilation of $\varepsilon$.

There is a one-to-one correspondence between the two operators of an adjunction pair, since, given a dilation $\delta$, there is a unique erosion (a.k.a. left adjoint)

$$\varepsilon(Y) = \bigvee \{X \in \mathcal{L} : \delta(X) \leq Y\}$$

(13)

---

1 As explained in [24, 23], the adjunction is related to a concept in poset and lattice theory called ‘Galois connection’. It is also related to residuation theory [9].
such that \((\varepsilon, \delta)\) is adjunction. Conversely, given an erosion \(\varepsilon\), there is a unique dilation (a.k.a. right adjoint)

\[
\delta(X) = \bigwedge \{Y \in L : \varepsilon(Y) \geq X\}
\]

such that \((\varepsilon, \delta)\) is adjunction. Adjunctions create operator duality pairs that are different than negation in the sense that one operator is the closest to being the inverse of the other.

**Lemma 1** Given an adjunction \((\varepsilon, \delta)\), the left (resp. right) adjoint of the operator \(\delta\) (resp. \(\varepsilon\)) is its greatest sub-inverse \(^2\) (resp. least super-inverse); as a corollary,

\[
\delta \varepsilon \leq \text{id} \leq \varepsilon \delta
\]

**Proof:** It can be deduced from (13) and (14). Q.E.D.

A large variety of useful lattice operators share two properties: increasing and idempotent. Such operators were called morphological filters in \([15, 23]\). We shall call them lattice projections of the order type, since they preserve the lattice ordering and are idempotent in analogy with the linear projections that preserve the algebraic structure of linear spaces and are idempotent. The most well-studied special cases of lattice projections are the openings and closings, each of which has an additional property. Specifically, openings are lattice projections that are anti-extensive, whereas closings are extensive projections. Combinations of such generalized filters have proven to be very useful for signal/image enhancement, simplification, segmentation, motion tracking, and object detection. From the composition of the erosion and dilation of any adjunction \((\varepsilon, \delta)\) we can generate a projection \(\alpha = \delta \varepsilon\) that is also an opening since \(\alpha(f) \leq f\) and \(\alpha^2 = \alpha\). Dually, any adjunction can also generate a closing projection \(\beta = \varepsilon \delta\).

### 2.3 Lattice-Ordered Monoids

A lattice \(M\) is often endowed with additional structure of the group type \([6]\). Namely, it may have an additional binary operation, called symbolically the ‘multiplication’ \(\star\), under which \((M, \star)\) is a semigroup or monoid or group.

Consider now an algebra \((M, \vee, \wedge, \star, \star')\) with four binary operations, which we call a lattice-ordered double monoid, where \((M, \vee, \wedge)\) is a lattice, \((M, \star)\) is a monoid whose ‘multiplication’ \(\star\) distributes over \(\vee\), and \((M, \star')\) is a dual monoid whose ‘multiplication’ \(\star'\) distributes over \(\wedge\). These distributivities imply that both \(\star\) and \(\star'\) are increasing. To the above definitions we add the word complete if \(M\) is a complete lattice and the distributivities involved are infinite. We call the resulting algebra a complete lattice-ordered double monoid, in short clodum \([33, 35]\). Previous works on minimax algebra and discrete-event dynamical systems have used alternative names \(^3\) for algebraic structures similar to the above definitions which emphasize semigroups and semirings instead of lattices. If \(\star = \star'\), we have a self-dual ‘multiplication’. This always happens if \((M, \star)\) is a group, i.e. a monoid where each element has an inverse; in this case we obtain a lattice-ordered group, and the group ‘multiplication’ \(X \mapsto A \star X\) is a lattice automorphism.

\(^2\)Given an increasing operator \(\psi\), we define an operator \(\phi\) to be a sub-inverse (resp. super-inverse) of \(\psi\) if \(\psi \phi \leq \text{id}\) (resp. \(\psi \phi \geq \text{id}\)).

\(^3\)In minimax algebra \([18]\) a semilattice is called a band and a lattice is called band with duality. Further, a semilattice-ordered semigroup is called a belt, and a lattice-ordered double semigroup is called a belt with duality. A belt \((B, \vee, \star)\) with an identity element for the operation \(\star\) and with an element \(e\) that is both the least element w.r.t. \(\leq\) and also a null, i.e. \(a \vee e = a\) and \(a \star e = e\), \(\forall a \in B\), is called a dioid in \([2]\); it is actually an idempotent semiring.
3 Representations of Vector and Signal Operations on Weighted Lattices

3.1 Algebraic Structures on the Scalars

We assume that all elements of the vectors, matrices, or signals involved in the description of the systems examined herein take their values from a set \( K \) of scalars, which in general will be a subset of \( \mathbb{R} = \mathbb{R} \cup \{-\infty, \infty\} \) with the natural ordering \( \leq \) of extended real numbers. We assume that the chain \((K, \leq)\) is universally bounded, i.e., contains its least \( \bot \) and greatest element \( \top \). For the weighted lattice model we need to equip \( K \) with four binary operations:

(A). The standard maximum or supremum \( \vee \) on \( \mathbb{R} \), which plays the role of a generalized ‘addition’.

(A’). The standard minimum or infimum \( \wedge \) on \( \mathbb{R} \), which plays the role of a generalized ‘dual addition’.

(M). A commutative generalized ‘multiplication’ \( \star \) under which: (i) \( K \) is a monoid with (‘unit’) identity element \( e \) and (‘zero’) null element \( \bot \), i.e.,

\[
a \star e = a, \quad a \star \bot = \bot, \quad \forall a \in K,
\]

and (ii) \( \star \) is a scalar dilation, i.e., distributes over any supremum:

\[
a \star \left( \bigvee_i x_i \right) = \bigvee_i a \star x_i
\]

(M’). A commutative ‘dual multiplication’ \( \star' \) under which: (i) \( K \) is a monoid with identity \( e' \) and null element \( \top \), i.e.,

\[
a \star' e' = a, \quad a \star' \top = \top, \quad \forall a \in K,
\]

and (ii) \( \star' \) is a scalar erosion, i.e., distributes over any infimum:

\[
a \star' \left( \bigwedge_i x_i \right) = \bigwedge_i a \star' x_i
\]

Under the above assumptions \((K, \vee, \wedge, \star, \star')\) becomes a scalar clodum\(^4\). This will be the most general and minimally required algebraic structure we consider for the set of scalars. We avoid degenerate cases by assuming that \( \vee \neq \star \) and \( \wedge \neq \star' \). However, \( \star \) may be the same as \( \star' \), in which case we have a self-dual ‘multiplication’.

A clodum \( K \) is called self-conjugate if it has a negation mapping each element \( a \) to its conjugate \( \overline{a} \) such that

\[
\bigvee_i a_i = \bigwedge_i \overline{a_i}, \quad \bigwedge_i b_i = \bigvee_i \overline{b_i}, \quad a \star \overline{b} = \overline{a \star \overline{b}}
\]

We assume that the conjugation distributes over any (possibly infinite) suprema and infima.

The set of scalars can be partitioned as \( K = K_{\text{fin}} \cup \{\bot, \top\} \); the members of \( K_{\text{fin}} \) are called the finite scalars, borrowing terminology from the archetypal case where \( K = \mathbb{R} \). This terminology is useful for cases where \((K_{\text{fin}}, \star)\) is a commutative group. Then, for each \( a \in K_{\text{fin}} \) there exists its ‘multiplicative inverse’ \( a^{-1} \) such that \( a \times a^{-1} = 1 \). Further, the ‘multiplication’ \( \star \) and its self-dual \( \star' \) (which coincide over \( K_{\text{fin}} \)) can be extended over the whole \( K \) by adding the rules in (16) and (18) involving the null elements. We call the resulting richer structure a complete lattice-ordered group, in short clog\(^5\) (In our work a scalar clodum or a clog will always be a chain.) Whenever \( K \) is a

\(^4\)In this work we assume commutative operations \( \star, \star' \) and that \( K \) is infinitely distributive as a lattice, but a general clodum does not have to be infinitely distributive and its operations \( \star, \star' \) do not have to be commutative.

\(^5\)A clog has a richer structure than a blog (bounded lattice-ordered group) defined in [18], because a clog is a complete and commutative blog.
clog, it becomes self-conjugate by setting

\[ \overline{c} = \begin{cases} a^{-1} & \text{if } \bot < a < \top \\ \top & \text{if } a = \bot \\ \bot & \text{if } a = \top \end{cases} \] (21)

In a clog the \( \star \) and \( \star' \) coincide in all cases with only one exception: the combination of the least and greatest elements. Thus, henceforth when a clodum \( K \) is a clog we can denote the algebra as \((K, \lor, \land, \star)\) using only one ‘multiplication’ operation and the case \( \bot \star \top \) will have value \( \bot \) (\( \top \)) if it is combined with other terms via a supremum (infimum).

### 3.2 Complete Weighted Lattices

Consider a nonempty collection \( W \) of mathematical objects, which will be our space; examples of such objects include the vectors in \( \mathbb{R}^n \) or signals in \( \text{Fun}(E, \mathbb{R}) \). Thus, we shall symbolically refer to the space elements as ‘vectors/signals’, although they may be arbitrary objects. Also, consider a clodum \((K, \lor, \land, \star, \star')\) of scalars. We define two operations among vectors/signals \( X, Y \) in \( W \): their supremum \( X \lor Y : W^2 \to W \) and infimum \( X \land Y : W^2 \to W \), which we denote using the same supremum symbol (\( \lor \)) and infimum symbol (\( \land \)) as in the clodum, hoping that the differences will be clear to the reader from the context. Further, we define two operations among any vector/signal \( X \) in \( W \) and any scalar \( c \) in \( K \): a ‘scalar multiplication’ \( c \times X : (K, W) \to W \) and a ‘scalar dual multiplication’ \( c \times' X : (K, W) \to W \), again by using the same symbols as in the clodum. Now, we define \( W \) to be a **weighted lattice** (WL) space over the clodum \( K \) if for all \( X, Y, Z \in W \) and \( a, b \in K \) all the axioms of Table 1 hold. Note that: (a) Under axioms L1-L9 and their duals \( L1' - L9' \), \( W \) is a distributive lattice with a least element \( (O) \) and a greatest element \( (I) \). (b) As detailed in [35], these axioms bear a striking similarity with those of a linear space. One difference is that the vector/ signal addition (+) of linear spaces is now replaced by two dual superpositions, the lattice supremum (\( \lor \)) and infimum (\( \land \)); further, the scalar multiplication (\( \times \)) of linear spaces is now replaced by two operations \( \star \) and \( \star' \) that are dual to each other. Only one major property of the linear spaces is missing from the weighted lattices: the existence of ‘additive inverses’; i.e., the supremum and infimum operations do not have inverses.

| Sup-Semilattice | Inf-Semilattice | Description |
|-----------------|-----------------|-------------|
| L1. \( X \lor Y \in W \) | L1'. \( X \land Y \in W \) | Closure of \( \lor, \land \) |
| L2. \( X \lor X = X \) | L2'. \( X \land X = X \) | Idempotence of \( \lor, \land \) |
| L3. \( X \lor Y = Y \lor X \) | L3'. \( X \land Y = Y \land X \) | Commutativity of \( \lor, \land \) |
| L4. \( X \lor (Y \lor Z) = (X \lor Y) \lor Z \) | L4'. \( X \land (Y \land Z) = (X \land Y) \land Z \) | Associativity of \( \lor, \land \) |
| L5. \( X \lor (X \land Y) = X \) | L5'. \( X \land (X \lor Y) = X \) | Absorption between \( \lor, \land \) |
| L6. \( Y \leq Y \iff Y = X \lor Y \) | L6'. \( Y \leq Y \iff Y = X \land Y \) | Consistency of \( \lor, \land \) with \( \leq \) |
| L7. \( O \lor X = X \) | L7'. \( I \land X = X \) | Identities of \( \lor, \land \) |
| L8. \( I \lor X = \top \) | L8'. \( O \land X = \bot \) | Absorbing Nulls of \( \lor, \land \) |
| L9. \( X \lor (Y \land Z) = (X \lor Y) \land (X \lor Z) \) | L9'. \( X \land (Y \lor Z) = (X \land Y) \lor (X \land Z) \) | Distributivity of \( \lor, \land \) |
| WL10. \( a \star X \in W \) | WL10'. \( a \star' X \in W \) | Closeup of \( \star, \star' \) |
| WL11. \( a \star (b \star X) = (a \star b) \star X \) | WL11'. \( a \star' (b \star' X) = (a \star' b) \star' X \) | Associativity of \( \star, \star' \) |
| WL12. \( e \star X = X \) | WL12'. \( e \star' X = X \) | Scalar Identities |
| WL13. \( \bot \star X = O \) | WL13'. \( \top \star' X = I \) | Scalar Nulls |
| WL14. \( a \star (X \lor Y) = a \star X \lor a \star Y \) | WL14'. \( a \star' (X \land Y) = a \star' X \land a \star' Y \) | Distributivity scalar-vector |
| WL15. \( (a \lor b) \star X = a \star X \lor b \star X \) | WL15'. \( (a \land b) \star' X = a \star' X \land b \star' X \) | Distributivity vector- scalar |

We define the weighted lattice \( W \) to be a **complete weighted lattice** (CWL) space if all the following hold:

(i) \( W \) is closed under any, possibly infinite, supreme and infima.
(ii) Its distributivities between supremum and infimum are of the infinite type.
(iii) The distributivities between the scalar operations $\star$ ($\star'$) and the supremum (infimum) are of the infinite type.

Note that, a (commutative and infinitely distributive) clodum is by itself a scalar complete weighted lattice over itself.

Consider a subset $\mathcal{A}$ of a complete weighted lattice $\mathcal{W}$ over a clodum $\mathcal{K}$. A space element $F$ is called a sup-$\star$ combination of points in $\mathcal{A}$ if there exists an indexed set of space elements $\{F_i\}$ in $\mathcal{A}$ and a corresponding set of scalars $\{a_i\}$ in $\mathcal{K}$ such that

$$F = \bigvee_i a_i \star F_i,$$

(22)

Dually, we can form an inf-$\star'$ combination $G = \bigwedge_i b_i \star' G_i$ of points $G_i$ in $\mathcal{A}$ with scalars $b_i$. The sup-$\star$ span of $\mathcal{A}$, denoted by $\text{span}_\vee(\mathcal{A})$, is the set of all sup-$\star$ combinations of elements in $\mathcal{A}$. If $\mathcal{A} = \emptyset$, then $\text{span}_\vee(\mathcal{A}) = \{O\}$. Dually, the inf-$\star'$ span $\text{span}_\wedge(\mathcal{A})$ is the set of all inf-$\star'$ combinations of elements in $\mathcal{A}$.

If the above sup-$\star$ and inf-$\star'$ combinations are based on a finite set of space elements, we shall call them max-$\star$ and min-$\star'$ combination, respectively. A set $\mathcal{S}$ in a complete weighted lattice is called max-$\star$ independent if each point $f \in \mathcal{S}$ is not a max-$\star$ combination of points in $\mathcal{S} \setminus \{f\}$; otherwise, the set is called max-$\star$ dependent. Dually for the min-$\star'$ (in)dependence.

A max-$\star$ independent subset $\mathcal{B}$ of a CWL $\mathcal{W}$ is called an upper basis for the space if each space element $F$ can be represented as a sup-$\star$ combination of basis elements:

$$F = \bigvee_i c_i \star B_i, \quad B_i \in \mathcal{B}$$

(23)

Dually, a min-$\star'$ independent subset $\mathcal{B}'$ of $\mathcal{W}$ is called a lower basis if $\mathcal{W} = \text{span}_\wedge(\mathcal{B}')$. If the space $\mathcal{W}$ is self-conjugate, then (23) implies that $\overline{F} = \bigwedge_i \overline{c_i} \star' \overline{B_i}$. Thus, if the space possesses an upper basis, it will possess a lower basis too. We conjecture that the upper and lower bases of a complete weighted lattice have the same cardinality, which is called the dimension of $\mathcal{W}$. If this is finite, the space is called finite-dimensional; otherwise, it is called infinite-dimensional.

Herein the underlying set of our space is a function space $\mathcal{W} = \text{Fun}(\mathcal{E}, \mathcal{K})$ where $\mathcal{E}$ is an arbitrary nonempty set playing the role of the domain of our functions. The values of these functions are from the clodum $(\mathcal{K}, \vee, \wedge, \star, \star')$ of scalars. Then, we extend pointwise the supremum, infimum and scalar multiplications of $\mathcal{K}$ to the functions: for $F, G \in \mathcal{W}$, $a \in \mathcal{K}$ and $x \in \mathcal{E}$

$$
\begin{align*}
(F \vee G)(x) &\triangleq F(x) \vee G(x) \\
(F \wedge G)(x) &\triangleq F(x) \wedge G(x) \\
(a \star F)(x) &\triangleq a \star F(x) \\
(a \star' F)(x) &\triangleq a \star' F(x)
\end{align*}
$$

(24)

Under the first two operations $\mathcal{W}$ becomes a complete infinitely distributive lattice that inherits many properties from the lattice structure of $\mathcal{K}$. The least ($O$) and greatest ($I$) elements of $\mathcal{W}$ are the constant functions $O(x) = \perp$ and $I(x) = \top$, $x \in \mathcal{E}$. Further, the scalar operations $\star$ and $\star'$, extended pointwise to functions, distribute over any suprema and infima, respectively. Thus, the function space $\text{Fun}(\mathcal{E}, \mathcal{K})$ is by construction a complete weighted lattice of functions over the clodum $\mathcal{K}$. The collection of all its properties creates a rich algebraic structure.

If the clodum $\mathcal{K}$ is self-conjugate, then we can extend the conjugation $(\cdot \overline{\cdot})$ to functions $F$ pointwise: $\overline{F}(x) \triangleq \overline{F}(x)$. In such a case we have a self-conjugate complete weighted lattice.

The space of vectors and the space of signals with values from $\mathcal{K}$ are special cases of function lattices. In particular, if $\mathcal{E} = \{1, 2, \ldots, n\}$, then $\mathcal{W}$ becomes the set of all $n$-dimensional vectors with elements from $\mathcal{K}$. If $\mathcal{E} = \mathbb{Z}$, then $\mathcal{W}$ becomes the set of all discrete-time signals with values from $\mathcal{K}$.

Elementary increasing operators on $\mathcal{W}$ are those that act as vertical translations (in short V-translations) of functions. Specifically, pointwise ‘multiplications’ of functions $F \in \mathcal{W}$ by scalars
a ∈ K yield the V-translations \( \tau_a \) and dual V-translations \( \tau'_a \), defined by

\[
[\tau_a(F)](x) \triangleq a \star F(x), \quad [\tau'_a(F)](x) \triangleq a \star' F(x)
\]

A function operator \( \psi \) on \( W \) is called (dual) V-translation invariant if it commutes with any (dual) V-translation \( \tau \), i.e., \( \psi \tau = \tau \psi \).

The above CWL \( W \) of functions contains an upper basis \( B \) and a lower basis \( B' \) which consist of the impulse functions \( q \) and the dual impulses \( q' \), respectively:

\[
q_y(x) \triangleq \begin{cases} e, & x = y \\ \perp, & x \neq y \end{cases}, \quad q'_y(x) \triangleq \begin{cases} e', & x = y \\ \top, & x \neq y \end{cases}
\]

Then, every function \( F(x) \) admits a representation as a supremum of V-translated impulses placed at all points or as infimum of dual V-translated impulses:

\[
F(x) = \bigvee_{y \in E} F(y) \star q_y(x) = \bigwedge_{y \in E} F(y) \star' q'_y(x)
\]

By using the V-translations and the basis representation of functions with impulses, we can build more complex increasing operators, as explained next.

Consider systems that are V-translation invariant dilations or erosions over \( W \). This invariance implies that they obey an interesting nonlinear superposition principle which has direct conceptual analogies with the well-known linear superposition. Specifically, we define \( \delta \) to be a dilation V-translation invariant (DVI) system iff for any \( c_i \in K \), \( F_i \in W \)

\[
\delta(\bigvee_{i \in J} c_i \star F_i) = \bigvee_{i \in J} c_i \star \delta(F_i)
\]

for any (finite or infinite) index set \( J \). We also define \( \varepsilon \) to be an erosion V-translation invariant (EVI) system iff

\[
\varepsilon(\bigwedge_{i \in J} c_i \star' F_i) = \bigwedge_{i \in J} c_i \star' \varepsilon(F_i)
\]

Compare the two above nonlinear superpositions with the linear superposition obeyed by a linear system \( \Gamma \):

\[
\Gamma(\sum_{i \in J} a_i \cdot F_i) = \sum_{i \in J} a_i \cdot \Gamma(F_i)
\]

where \( J \) is a finite index set, \( a_i \) are constants from a field (of real or complex numbers) and \( F_i \) are field-valued signals from a linear space.

The structure of a DVI or EVI system’s output is simplified if we express it via the system’s impulse responses, defined next. Given a dilation system \( \delta \), its impulse response map is the map \( H : E \rightarrow \text{Fun}(E, K) \) defined at each \( y \in E \) as the output function \( H(x, y) \) from \( \delta \) when the input is the impulse \( q_y(x) \). Dually, for an erosion operator \( \varepsilon \) we define its dual impulse response map \( H' \) via its outputs when excited by dual impulses: for \( x, y \in E \)

\[
H(x, y) \triangleq \delta(q_y)(x), \quad H'(x, y) \triangleq \varepsilon(q'_y)(x)
\]

Applying a DVI operator \( \delta \) or an EVI operator \( \varepsilon \) to (27) and using the definitions in (31) proves the following unified representation for all V-translation invariant dilation or erosion systems.

**Theorem 1** (a) A system \( \delta \) on \( W \) is DVI, i.e. obeys the sup-\( \star \) superposition of (28), if and only if its output can be expressed as

\[
\delta(F)(x) = \bigvee_{y \in E} H(x, y) \star F(y)
\]
where $H$ is its impulse response map in (31). (b) A system $\varepsilon$ on $W$ is EVI, i.e. obeys the inf-$\star'$ superposition of (29), if and only if its output can be expressed as

$$
\varepsilon(F)(x) = \bigwedge_{y \in E} H'(x,y) \star' F(y)
$$

where $H'$ is its dual impulse response map in (31).

In the case of a signal space where $E = \mathbb{Z}$, the operations in (32) and (33) are like \textit{time-varying nonlinear convolutions} where a dilation (resp. erosion) system’s output is obtained as supremum (resp. infimum) of various impulse response signals produced by exciting with impulses at all points and weighted by the input signal values via a semigroup $\star$-‘multiplication’.

### 3.3 Weighted Lattice of Vectors

Consider now the nonlinear vector space $W = \mathcal{K}^n$, equipped with the pointwise partial ordering $x \leq y$, supremum $x \vee y = [x_i \vee y_i]$ and infimum $x \wedge y = [x_i \wedge y_i]$ between any vectors $x, y \in W$. Then, $(W, \vee, \wedge, \star, \star')$ is a complete weighted lattice. Elementary increasing operators are the vector $V$-translations $\tau_a(x) = a \star x = [a \star x_i]$ and their duals $\tau'_a(x) = a \star' x$, which ‘multiply’ a scalar $a$ with a vector $x$ componentwise. A vector transformation on $W$ is called (dual) $V$-translation invariant if it commutes with any vector (dual) $V$-translation.

By defining as ‘impulse functions’ the impulse vectors $q_i = [q_i(j)]$ and their duals $q'_i = [q'_i(j)]$, where the index $i$ signifies the position of the identity, each vector $x = [x_1, ..., x_n]^T$ can be represented as a max of $V$-translated impulse vectors or as a min of $V$-translated dual impulse vectors:

$$
x = \bigvee_{i=1}^n x_i \star q_i = \bigwedge_{i=1}^n x_i \star' q'_i
$$

More complex examples of increasing operators on this vector space are the max-$\star$ and the min-$\star'$ ‘multiplications’ of a matrix $M$ with an input vector $x$,

$$
\delta_M(x) \triangleq M \boxtimes x, \quad \varepsilon_M(x) \triangleq M \boxtimes' x
$$

which are, respectively, a vector dilation and a vector erosion. These two nonlinear matrix-vector ‘products’ are the prototypes of any vector transformation that obeys a sup-$\star$ or an inf-$\star'$ superposition, as proven next.

**Theorem 2** (a) Any vector transformation on the complete weighted lattice $W = \mathcal{K}^n$ is DVI, i.e. obeys the sup-$\star$ superposition of (28), iff it can be represented as a matrix-vector max-$\star$ product $\delta_M(x) = M \boxtimes x$ where $M = [m_{ij}]$ with $m_{ij} = \{\delta(q_j)\}_i$.

(b) Any vector transformation on $\mathcal{K}^n$ is EVI, i.e. obeys the inf-$\star'$ superposition of (29), iff it can be represented as a matrix-vector min-$\star'$ product $\varepsilon_M(x) = M \boxtimes' x$ where $M = [m_{ij}]$ with $m_{ij} = \{\varepsilon(q'_j)\}_i$.

**Proof:** This is a special case of Theorem 1 where the domain points $x, y \in E$ become indices $i, j \in \{1, ..., n\}$ and the impulse response values $H(x,y)$ become matrix elements $m_{ij}$. Thus, the operations (32) and (33) become the max-$\star$ and min-$\star'$ products (35) of input vectors with the matrix $M = [m_{ij}]$.

Given a vector dilation $\delta(x) = M \boxtimes x$ with matrix $M = [m_{ij}]$, there corresponds a unique adjoint vector erosion $\varepsilon$ so that $(\varepsilon, \delta)$ is a \textit{vector adjunction} on $W$, i.e.

$$
\delta(x) \leq y \iff x \leq \varepsilon(y)
$$

(We seek adjunctions because they can easily generate projections.) We can find the adjoint vector erosion by decomposing both vector operators based on scalar operators $(\zeta, \eta)$ that form a \textit{scalar adjunction} on $\mathcal{K}$:

$$
\eta(a, v) \leq w \iff v \leq \zeta(a, w)
$$

$$
where H is its impulse response map in (31). (b) A system ε on W is EVI, i.e. obeys the inf-⋆ superposition of (29), if and only if its output can be expressed as

\[ ε(F)(x) = \bigwedge_{y \in E} H'(x,y) \star' F(y) \] (33)

where H' is its dual impulse response map in (31).

In the case of a signal space where E = Z, the operations in (32) and (33) are like \textit{time-varying nonlinear convolutions} where a dilation (resp. erosion) system’s output is obtained as supremum (resp. infimum) of various impulse response signals produced by exciting with impulses at all points and weighted by the input signal values via a semigroup ⋆-‘multiplication’.

### 3.3 Weighted Lattice of Vectors

Consider now the nonlinear vector space W = Kn, equipped with the pointwise partial ordering x ≤ y, supremum x ∨ y = [x_i ∨ y_i] and infimum x ∧ y = [x_i ∧ y_i] between any vectors x, y ∈ W. Then, (W, ∨, ∧, ⋆, ⋆’) is a complete weighted lattice. Elementary increasing operators are the vector V-translations τ_a(x) = a ⋆ x = [a ⋆ x_i] and their duals τ'_a(x) = a ⋆' x, which ‘multiply’ a scalar a with a vector x componentwise. A vector transformation on W is called (dual) V-translation invariant if it commutes with any vector (dual) V-translation.

By defining as ‘impulse functions’ the impulse vectors q_i = [q_i(j)] and their duals q'_i = [q'_i(j)], where the index i signifies the position of the identity, each vector x = [x_1, ..., x_n]^T can be represented as a max of V-translated impulse vectors or as a min of V-translated dual impulse vectors:

\[ x = \bigvee_{i=1}^n x_i \star q_i = \bigwedge_{i=1}^n x_i \star' q'_i \] (34)

More complex examples of increasing operators on this vector space are the max-⋆ and the min-⋆’ ‘multiplications’ of a matrix M with an input vector x,

\[ δ_M(x) \triangleq M \boxtimes x, \quad ε_M(x) \triangleq M \boxtimes' x \] (35)

which are, respectively, a vector dilation and a vector erosion. These two nonlinear matrix-vector ‘products’ are the prototypes of any vector transformation that obeys a sup-⋆ or an inf-⋆’ superposition, as proven next.

**Theorem 2** (a) Any vector transformation on the complete weighted lattice W = Kn is DVI, i.e. obeys the sup-⋆ superposition of (28), iff it can be represented as a matrix-vector max-⋆ product δ_M(x) = M \boxtimes x where M = [m_{ij}] with m_{ij} = {δ(q_j)}_i.

(b) Any vector transformation on Kn is EVI, i.e. obeys the inf-⋆’ superposition of (29), iff it can be represented as a matrix-vector min-⋆’ product ε_M(x) = M \boxtimes' x where M = [m_{ij}] with m_{ij} = {ε(q'_j)}_i.

**Proof:** This is a special case of Theorem 1 where the domain points x, y ∈ E become indices i, j ∈ {1, ..., n} and the impulse response values H(x,y) become matrix elements m_{ij}. Thus, the operations (32) and (33) become the max-⋆ and min-⋆’ products (35) of input vectors with the matrix M = [m_{ij}].

Given a vector dilation δ(x) = M \boxtimes x with matrix M = [m_{ij}], there corresponds a unique adjoint vector erosion ε so that (ε, δ) is a vector adjunction on W, i.e.

\[ δ(x) \leq y \iff x \leq ε(y) \] (36)

(We seek adjunctions because they can easily generate projections.) We can find the adjoint vector erosion by decomposing both vector operators based on scalar operators (ζ, η) that form a scalar adjunction on K:

\[ η(a, v) \leq w \iff v \leq ζ(a, w) \] (37)
If we use as scalar ‘multiplication’ a commutative binary operation \( \eta(a, v) = a \star v \) that is a dilation on \( K \), its scalar adjoint erosion becomes
\[
\zeta(a, w) = \sup \{ v \in K : a \star v \leq w \}
\]
which is a (possibly non-commutative) binary operation on \( K \). Then, the original vector dilation \( \delta(x) = M \bullet x \) is decomposed as
\[
\{ \delta(x) \}_i = \bigvee_j \eta(m_{ij}, x_j) = m_{ij} \star x_j, \quad i = 1, \ldots, n
\]
whereas its adjoint vector erosion is decomposed as
\[
\{ \varepsilon(y) \}_j = \bigwedge_i \zeta(m_{ji}, y_i), \quad j = 1, \ldots, n
\]
We call the latter the min-\( \zeta \)-matrix-vector multiplication and denote it as
\[
\varepsilon(y) = M^T \square'_\zeta y
\]
where the symbol \( \square'_\zeta \) denotes the following nonlinear product of a matrix \( A = [a_{ij}] \) with a matrix \( B = [b_{ij}] \):
\[
\{ A \square'_\zeta B \}_{ij} \triangleq \bigwedge_k \zeta(a_{ik}, b_{kj})
\]
Further, if \( K \) is a clog, it can be shown that \( \zeta(a, w) = \overline{a} \star' w \) and hence
\[
\varepsilon(y) = M^* \boxdot' \eta y,
\]
where \( M^* \) is the conjugate transpose of \( M = [m_{ij}] \):
\[
M^* \triangleq \overline{M}^T = [\overline{m_{ji}}]
\]
Dually, given a vector erosion \( \varepsilon'(y) = M \boxdot' y \) we can find its adjoint vector dilation \( \delta' \) by starting from the ‘dual multiplication’ \( \zeta(a, w) = a \star' w \) as a scalar erosion and finding its right adjoint as the scalar dilation
\[
\eta(a, v) = \inf \{ w : a \star' w \geq v \}
\]
Then the min-\( \zeta \) matrix-vector multiplication \( \varepsilon'(y) = M \bullet' y \) with
\[
\{ \varepsilon'(y) \}_i = \bigwedge j \zeta(m_{ij}, y_j) = m_{ij} \star' y_j, \quad i = 1, \ldots, n
\]
has as adjoint the max-\( \eta \) matrix-vector multiplication \( \delta'(x) \) where
\[
\{ \delta'(x) \}_j \triangleq \bigvee_i \eta(m_{ji}, x_i), \quad j = 1, \ldots, n
\]
We denote this max-\( \eta \) matrix-vector multiplication as
\[
\delta'(x) = M^T \square_\eta x
\]
where the symbol \( \square_\eta \) denotes the following nonlinear product of a matrix \( A = [a_{ij}] \) with a matrix \( B = [b_{ij}] \):
\[
\{ A \square_\eta B \}_{ij} \triangleq \bigvee_k \eta(a_{ik}, b_{kj})
\]
Further, if \( K \) is a clog, it can be shown that \( \eta(a, v) = \overline{a} \star v \) and hence
\[
\delta'(x) = M^* \boxdot x
\]
3.4 Weighted Lattice of Signals

Consider the set \( W = \text{Fun}(\mathbb{Z}, \mathcal{K}) \) of all discrete-time signals \( f : \mathbb{Z} \rightarrow \mathcal{K} \) with values from \( \mathcal{K} \). Equipped with pointwise supremum \( \vee \) and infimum \( \wedge \), and two pointwise scalar multiplications (\( \star \) and \( \star' \)), this becomes a complete weighted lattice \( W \) with partial order the pointwise signal relation \( \leq \). The signal translations are the operators \( \tau_{k,v}(f)(t) = f(t-k) \star v \), where \((k,v) \in \mathbb{Z} \times \mathcal{K} \) and \( f(t) \) is an arbitrary input signal. Similarly, we define dual signal translations \( \tau'_{k,v}(f)(t) = f(t-k) \star' v \).

A signal operator on \( W \) is called (dual) translation-invariant (DTI) systems. Applying \( \Delta \) to an input signal \( f \) is both DVI in the sense of (28) and time-invariant. We call such operators (dual) translation invariant. Consider two elementary signals, called the impulse \( q \) and the dual impulse \( q' \):

\[
q(t) \triangleq \left\{ \begin{array}{ll} e, & t = 0 \\ \bot, & t \neq 0 \end{array} \right., \quad q'(t) \triangleq \left\{ \begin{array}{ll} e', & t = 0 \\ \top, & t \neq 0 \end{array} \right.,
\]

Then every signal \( f \) can be represented as a supremum of translated impulses or as infimum of dual translated impulses:

\[
f(t) = \bigvee_{k} f(k) \star q(t-k) = \bigwedge_{k} f(k) \star' q'(t-k)
\]

Consider now operators \( \Delta \) on \( W \) that are dilations and translation-invariant in the above sense. Then \( \Delta \) is both DVI in the sense of (28) and time-invariant. We call such operators dilation translation-invariant (DTI) systems. Applying \( \Delta \) to an input signal \( f \) decomposed as in (19) yields its output as the sup-\( \star \) convolution \( \bigodot \) of the input with the system’s impulse response \( h = \Delta(q) \):

\[
\Delta(f)(t) = (f \bigodot h)(t) = \bigvee_{k \in \mathbb{Z}} f(k) \star h(t-k)
\]

Conversely, every sup-\( \star \) convolution is a DTI system. As done for the vector operators, we can also build signal operator pairs \( (\mathcal{E}, \Delta) \) that form adjunctions:

\[
\Delta(f) \leq g \iff f \leq \mathcal{E}(g)
\]

Given \( \Delta \) we can find its left adjoint \( \mathcal{E} \) from scalar adjunctions \((\zeta, \eta)\). Thus, by (37) and (38), if \( \eta(h, f) = h \star f \), the adjoint signal erosion becomes

\[
\mathcal{E}(g)(t) = \bigwedge_{\ell \in \mathbb{Z}} \zeta[h(\ell - t), g(\ell)]
\]

Further, if \( \mathcal{K} \) is a clog, then

\[
\mathcal{E}(g)(t) = \bigwedge_{\ell \in \mathbb{Z}} g(\ell) \star' \overline{h}(\ell - t)
\]

Dually, if we start from an operator \( \mathcal{E} \) on \( W \) that is erosion and translation-invariant, then \( \mathcal{E} \) is both EVI in the sense of (29) and time-invariant. We call such operators erosion translation-invariant (ETI) systems. Applying \( \mathcal{E} \) to an input signal \( g \) decomposed as in (19) yields the output as the inf-\( \star' \) convolution \( \bigodot' \) of the input with the system’s dual impulse response \( h' = \Delta(q') \):

\[
\mathcal{E}(g)(t) = (g \bigodot h')(t) = \bigwedge_{k \in \mathbb{Z}} g(k) \star' h'(t-k)
\]

Setting \( \zeta(h, g) = h \star' g \) and using (37), (41) yields the adjoint signal dilation

\[
\Delta(f)(t) = (f \bigodot h)(t) = \bigvee_{\ell \in \mathbb{Z}} \eta[h(\ell - t), f(\ell)]
\]

which, if \( \mathcal{K} \) is a clog, becomes

\[
\Delta(f)(t) = (f \bigodot h)(t) = \bigvee_{\ell \in \mathbb{Z}} f(\ell) \star \overline{h}(\ell - t)
\]

An outcome of the previous discussion is:
**Theorem 3** (a) An operator $\Delta$ on a CWL $W$ of signals is a dilation translation invariant (DTI) system iff it can be represented as the sup-$\star$ convolution of the input signal with the system’s impulse response $h = \Delta(q)$. (b) An operator $E$ on $W$ is an erosion dual-translation invariant (ETI) system iff it can be represented as the inf-$\star'$ convolution of the input signal with the system’s dual impulse response $h' = E(q')$.

4 State and Output Responses

Based on the state-space model of a max-$\star$ dynamical system [2], we can compute its state response and output response if we know its transition matrix:

$$\Phi(t_2, t_1) \triangleq \begin{cases} A(t_2) \boxdot \cdots \boxdot A(t_1 + 1) & \text{if } t_2 > t_1 \\ I_n & \text{if } t_2 = t_1 \end{cases}$$

(57)

for $t_2 \geq t_1$, where $I_n$ is the $n \times n$ identity matrix in max-$\star$ matrix algebra that has values equal to the identity element $e$ on its diagonal and least elements (nulls) $\perp$ off-diagonally. The importance of $\Phi$ is obvious by noticing that for a null input, the solution of the homogeneous state equation

$$x(t) = A(t) \boxdot x(t - 1)$$

equals

$$x(t) = \Phi(t, 0) \boxdot x(0)$$

(59)

The transition matrix obeys a semigroup property:

$$\Phi(t_2, t_1) \boxdot \Phi(t_1, t_0) = \Phi(t_2, t_1), \quad t_0 \leq t_1 \leq t_2$$

(60)

4.1 Time-Varying Systems

By using induction on (2) we can find the state and output responses of the general time-varying nonhomogeneous system; for $t = 0, 1, 2, ...$,

$$x(t) = \Phi(t, 0) \boxdot x(0) \lor \left( \bigvee_{k=1}^{t} \Phi(t, k) \boxdot B(k) \boxdot u(k) \right)$$

$$y(t) = \underbrace{C(t) \boxdot \Phi(t, 0) \boxdot x(0)}_{y_{ni}(t) \triangleq \text{’null’-input resp.}} \lor \left( \bigvee_{k=1}^{t} \underbrace{C(t) \boxdot \Phi(t, k) \boxdot B(k) \boxdot u(k)}_{y_{ns}(t) \triangleq \text{’null’-state resp.}} \right) \lor D(t) \boxdot u(t)$$

(61)

where the supremum $\bigvee_{k=1}^{t}$ is null if $t < 1$. Henceforth we shall assume that in practice $u(0)$ is null (i.e. the input starts being active from $t \geq 1$) and use $x(0)$ as the system’s effective initial condition. (Otherwise, we use $x(-1)$ as initial condition.) Thus, the output response is found to consist of two parts: (i) the ‘null’-input response which is due only to the initial conditions $x(0)$ and assumes a null input, i.e. equal to $u(t) = \perp$, and (ii) the ‘null’-state response which is due only to the input $u(t)$ and assumes null initial conditions, i.e. $x(0) = \perp$.

We observe that the ‘null’-state response is essentially a time-varying sup-$\star$ matrix convolution of the input with a weight matrix $H(t, k) \triangleq C(t) \boxdot \Phi(t, k) \boxdot B(k)$:

$$y_{ns}(t) = \bigvee_{k=0}^{\infty} H(t, k) \boxdot u(k)$$

(62)

This is a matrix version of the scalar time-varying sup-$\star$ convolution in [32].
4.2 Time-Invariant Systems

Let the matrices $A, B, C, D$ be constant. Then, the max-$\star$ state equations become:

$$
\begin{align*}
    x(t) &= A \bigstar x(t-1) \lor B \bigstar u(t) \\
    y(t) &= C \bigstar x(t) \lor D \bigstar u(t)
\end{align*}
$$

(63)

Since the transition matrix simplifies to

$$
\Phi(t_2, t_1) = A^{(t_2-t_1)}
$$

(64)

where $A^{(t)}$ denotes the $t$-fold max-$\star$ matrix product of $A$ with itself for $t \geq 1$ and $A^{(0)} = I_n$, the solutions of the constant-matrix state equations become

$$
\begin{align*}
    x(t) &= A^{(t)} \bigstar x(0) \lor \left( \bigvee_{k=1}^{t} A^{(t-k)} \bigstar B \bigstar u(k) \right) \\
    y(t) &= C \bigstar A^{(t)} \bigstar x(0) \lor C \bigstar \left( \bigvee_{k=1}^{t} A^{(t-k)} \bigstar B \bigstar u(k) \right) \lor D \bigstar u(t)
\end{align*}
$$

(65)

By representing the matrix-vector $\bigstar$-product as a dilation operator $x \mapsto \delta_A(x) = A \bigstar x$, we can express the state equations (63) with vector operators:

$$
\begin{align*}
    x(t) &= \delta_A(x(t-1)) \lor \delta_B[u(t)] \\
    y(t) &= \delta_C[x(t)] \lor \delta_D[u(t)]
\end{align*}
$$

(66)

and the state and output responses (65) in operator form:

$$
\begin{align*}
    x(t) &= \delta_A^t[x(0)] \lor \left( \bigvee_{k=1}^{t} \delta_A^{t-k} \delta_B[u(k)] \right) \\
    y(t) &= \delta_C \delta_A^t[x(0)] \lor \delta_C \left( \bigvee_{k=1}^{t} \delta_A^{t-k} \delta_B[u(k)] \right) \lor \delta_D[u(t)]
\end{align*}
$$

(67)

For single-input single-output (SISO) systems the mapping $u(t) \mapsto y_{ns}(t)$ can be viewed as a translation invariant dilation system $\Delta$. Hence, the ‘null’-state response can be found as the sup-$\star$ convolution of the input with the system’s impulse response $h = \Delta(q)$:

$$
y_{ns}(t) = \Delta(u)(t) = (u \bigstar h)(t) = \bigvee_k h(t-k) \star u(k)
$$

(68)

The impulse response can be found from (65) by setting initial conditions equal to null and the input $u(t) = q(t)$:

$$
h(t) = \begin{cases} 
    \bot, & t < 0 \\
    (C \bigstar B) \lor D, & t = 0 \\
    C \bigstar A^{(t)} \bigstar B, & t > 0
\end{cases}
$$

(69)

where in this case $D$ is a scalar, $C$ is a row vector and $B$ a column vector. The last two results can be easily extended to multi-input multi-output (MIMO) systems by using an impulse response matrix as in (62).
5 Solving Max-$\star$ Equations

Consider a scalar clodum \((K, \vee, \wedge, \star, \star')\), a matrix \(A \in K^{m \times n}\) and a vector \(b \in K^m\). The set of solutions of the max-$\star$ equation

\[ A \boxplus x = b \]  

over \(K\) is either empty or forms a sup-semilattice. In [18] necessary and sufficient conditions are given for the existence and properties of such solutions. A related problem in applications of max-plus algebra to scheduling is when a vector \(x\) represents start times, a vector \(b\) represents finish times and the matrix \(A\) represents processing delays. Then, if \(A \boxplus x = b\) does not have an exact solution, it is possible to find the optimum \(x\) such that we minimize a norm of the earliness subject to zero lateness. We generalize this problem from max-plus to max-$\star$ algebra. The optimum will be the solution of the following constrained minimization problem:

\[ \text{Minimize} \|A \boxplus x - b\| \text{ s.t. } A \boxplus x \leq b \]  

where the norm \(\| \cdot \|\) is either the \(\ell_\infty\) or the \(\ell_1\) norm. While the two above problems have been solved in [18] by using minimax algebra over the max-plus \((K, \vee, \wedge, +)\) or general clogs, we provide next an alternative and shorter proof of both results using adjunctions and for the general case when \(K\) may not be a clog.

Theorem 4 Consider a vector dilation \(\delta(x) = A \boxplus x\) over a scalar clodum \(K\) and let \(\varepsilon\) be its adjoint vector erosion. (a) If Eq. (70) has a solution, then

\[ \hat{x} = A^T \boxtimes \zeta b \]  

is its greatest solution, where \(\zeta\) is the scalar adjoint erosion \([35]\) of \(\star\).

(b) If \(K\) is a clog, the solution \([72]\) becomes

\[ \hat{x} = A^* \boxtimes' b \]  

(c) The solution to the minimization problem \([71]\) is generally \([72]\), or \([73]\) in the special case of a clog.

Proof: (a),(c): We showed in \([10], [11]\) that the adjoint vector erosion of \(\delta(x) = A \boxplus x\) is generally equal to \(\varepsilon(y) = A^T \boxtimes \zeta y\). Thus, the solution \([72]\) has the form of an erosion, and Lemma 1 completes the proof. Namely, by \([13]\), this has the property

\[ \varepsilon(b) = \bigvee \{x : \delta(x) \leq b\} \]  

The above immediately suggests that if \(\varepsilon(b)\) is a solution, then it is the greatest solution. If not, then the difference \(b - \delta(\varepsilon(b))\) is nonnegative and has the smallest \(\ell_\infty\) or \(\ell_1\) norm. (b) For a clog, the scalar adjoint erosion of \(\star\) is \(\zeta(a, w) = \overline{a} \star' w\) which gives \([72]\) the expression \([73]\). Q.E.D.

A main idea behind the method for solving \([71]\) is to consider vectors \(x\) that are sub-solutions in the sense that \(A \boxplus x \leq b\) and find the greatest such sub-solution. The set of sub-solutions forms a sup-semilattice whose supremum equals \(\hat{x}\), which yields either the greatest exact solution of \([70]\) or an optimum approximate solution in the sense of \([71]\). Another attractive aspect of the adjunction-based solution is that it creates a lattice projection onto the max-$\star'$ span of the columns of \(A\) via the opening \(\delta(\varepsilon(b)) \leq b\) that best approximates \(b\) from below.

Further, by using adjunctions and duality, the CWL framework allows us to easily formulate and solve a dual problem of solving the min-$\star'$ equation

\[ A \boxtimes' y = b \]  

either exactly if it has a solution, or by finding super-solutions \(y\) in the sense that \(A \boxplus' y \geq b\) and picking the smallest such super-solution. Approximate solutions of (75) can always be found by solving the following problem

\[
\text{Minimize } \|A \boxplus' y - b\| \text{ s.t. } A \boxplus' y \geq b
\]

(76)

where the norm \(\| \cdot \|\) is either the \(\ell_\infty\) or the \(\ell_1\) norm. The set of super-solutions forms a semigroup under vector \(\land\) whose infimum yields either the smallest exact solution of (75) if it exists or an optimum approximate solution in the sense of (76); this infimum is

\[
y = A^T \Box \eta b
\]

(77)

where \(\eta\) is the scalar adjoint dilation (44) of \(*'\). For a clog this becomes

\[
y = A^\ast \Box b
\]

(78)

By viewing \(\varepsilon(y) = A \boxplus' y\) as a vector erosion, the operation in (77) or (78) is its corresponding adjoint vector dilation \(\delta\). This adjunction yields as best approximation the closing \(\varepsilon(\delta(b)) \geq b\) which is a lattice projection that comes optimally close to \(b\) from above.

6 Spectral Analysis in Max-\(*\) Algebra

There has been significant progress on eigenvalue analysis for the max-plus semiring \((\mathbb{R} \cup \{-\infty\}, \lor, +)\) from [18, 14]. Herein, we extend some of the main results to any scalar clodum \(K\) even in cases where the ‘multiplications’ do not have inverses. The only constraint on the clodum \(K\) is to be radicable w.r.t. operations \(*, *'\); i.e., for each \(a \in K\) and integer \(p \geq 2\) there is some \(x \in K\) such that its \(p\)-fold \(\ast\) multiplication with itself equals \(a\), i.e. \(x^p \triangleq x \ast x \ast \cdots \ast x = a\).

For the max-\(*\) eigenvalue analysis we shall use the max-\(*\) subalgebra \((K \setminus \{\top\}, \lor, *)\); practical, we assume that all scalars and matrix elements are less than \(\top\). Consider a \(n \times n\) matrix \(A = [a_{ij}]\), \(n > 1\). This can be represented by a directed weighted graph \(\text{Gr}(A)\) that has \(n\) nodes and arcs connecting pairs of nodes \((i, j)\) if the corresponding weights \(a_{ij} > \bot\). If \(\text{Gr}(A)\) is strongly connected, i.e. if there is a path from every node to every other node, then \(A\) is called irreducible. Consider a path on the graph, i.e., a sequence of nodes \(\pi = (i_0, i_1, ..., i_t)\) with length \(\ell(\pi) = t\); its weight is defined by \(w(\pi) \triangleq a_{i_{0}i_{1}} \ast a_{i_{1}i_{2}} \ast \cdots \ast a_{i_{t-1}i_{t}}\). A path \(\sigma\) is called a cycle if \(i_0 = i_t\); the cycle is elementary if the nodes \(i_0, ..., i_{t-1}\) are distinct. For any cycle \(\sigma\) we define its cycle mean\(^6\) by \(w(\sigma)^{(1/\ell(\sigma))}\). Let

\[
\lambda(A) \triangleq \bigvee \text{all cycles } \sigma \text{ of } A \quad w(\sigma)^{(1/\ell(\sigma))}
\]

(79)

be the maximum cycle mean in \(\text{Gr}(A)\). Since \(\text{Gr}(A)\) has \(n\) nodes, only elementary cycles with length \(\leq n\) need be considered in (79). There is also at least one cycle whose average weight coincides with the maximum value \(\lambda(A)\); such a cycle is called critical. The existence of \(\lambda(A)\) is guaranteed if \((K, \ast)\) is radicable.

The max-\(*\) eigenproblem for the matrix \(A\) consists of finding its eigenvalues \(\lambda\) and eigenvectors \(v \neq \bot\) such that

\[
A \boxplus v = \lambda \ast v
\]

(80)

The maximum cycle mean \(\lambda(A)\) plays a fundamental role in this eigenproblem for many reasons [18, 14]: It is the largest eigenvalue of \(A\) and is the only eigenvalue whose corresponding eigenvectors may be finite. Thus, \(\lambda(A)\) is called the principal eigenvalue of \(A\). Some further properties include the following. Define the metric matrix generated by \(A\) as the series

\[
\Gamma(A) \triangleq \bigvee_{k=1}^{\infty} A^{(k)}
\]

(81)

\(^6\)For the max-plus clog \((\mathbb{R}, \lor, \land, +)\) the mean of a cycle \(\sigma\) is given by \(w(\sigma)/\ell(\sigma)\), whereas for the max-product clog \(([0, \infty], \lor, \land, \ast)\) it is given by \(w(\sigma)^{1/\ell(\sigma)}\).
If it converges, it conveys very useful information since its elements equal the weights of the heaviest paths of any length for all pairs of nodes (like a graph of longest distances), and its columns can provide eigenvectors \([18, 14]\). However, its existence is controlled by \(\lambda(A)\) as explained by

**Lemma 2** Assume a \(n \times n\) matrix \(A\) with elements from \(K \setminus \{\top\}\). The infinite series \((87)\) converges to a matrix \(\Gamma(A) = [\gamma_{ij}]\) with all \(\gamma_{ij} < \top\) iff \(\lambda(A) \leq e\), in which case for all \(t \geq 1\)

\[
A^{(t)} \leq \Gamma(A) = A \vee A^{(2)} \vee \ldots \vee A^{(n)}
\]

(82)

If \(A\) is also irreducible, then all \(\gamma_{ij} > \top\).

**Proof:** We extend the results of \([18, 14]\) to a general radicable clodum. Assume first clodums with \(e < \top\). If \(\lambda(A) \leq e\), then a path \(\pi\) between any nodes \(i, j\) of length > \(n\) contains cycles, all whose weights \(\leq e\). By deleting these cycles we can create only heavier subpaths \(\pi'\) of length \(\leq n\), i.e. \(w(\pi') \geq w(\pi)\). Given the finite only number of paths (without cycles) between any nodes \(i, j\), if a path exists, then a heaviest such path also exists with length \(\leq n\) and weight \(\gamma_{ij} < \top\); if no path exists, then \(\gamma_{ij} = \top\). If \(\lambda(A) > e\), then there exists a cycle with weight \(> e\) which will drive at least one element in \(A^{(t)}\) unbounded (i.e. \(\top\)) as \(t \to \infty\). Thus, \((82)\) holds iff \(\lambda(A) \leq e\). If \(A\) is also irreducible, i.e. \(\text{Gr}(A)\) is strongly connected, then a path exists between any nodes \(i, j\) and hence each \(\gamma_{ij} > \top\). Finally, the case of clodums with \(e = \top\) is covered because then \(\lambda(A) < e\) since we assumed that all matrix elements are \(< \top\).

Q.E.D.

By using lattice duality we can also solve the dual eigenproblem

\[
A \star' y = \lambda' \star' y
\]

(83)

where all elements of the matrix \(A\) and the dual eigenvectors as well as the dual eigenvalues \(\lambda'\) assume values only from \(K \setminus \{\bot\}\). The dual principal eigenvalue, denoted by \(\lambda'(A)\), is the smallest of all dual eigenvalues and can be found as the minimum cycle mean of \(A\).

### 7 Causality, Stability

Assume for brevity SISO systems. (Our results can be easily extended for MIMO systems.) Assume also that systems’ matrices are constant. A useful bound for signals \(f(t)\) processed by max-\(\star\) systems is their supremal value \(\bigvee_t f(t)\). We call max-\(\star\) systems **upper-stable** iff an upper bounded input and initial condition yields an upper bounded output, i.e. if

\[
x(0) < \top \text{ and } \bigvee_t u(t) < \top \implies \bigvee_t y(t) < \top
\]

(84)

If initial conditions are null and \((84)\) is satisfied, we call the system bounded-input bounded-output (BIBO) upper-stable. Dually, min-\(\star\)' systems are called **lower-stable** iff a lower bounded input and initial condition yields a lower bounded output, i.e. if

\[
x(0) > \bot \text{ and } \bigwedge_t u(t) > \bot \implies \bigwedge_t y(t) > \bot
\]

(85)

A max-\(\star\) (min-\(\star\)') dynamical system with null initial conditions can be viewed as a DTI (ETI) system mapping the input \(u\) to the output which is the sup-\(\star\) (inf-\(\star\)') convolution \(y = u \circ h\) \((y = u \circ' h')\) of the input with the (dual) impulse response \(h\) \((h')\). The following theorem provides us with simple algebraic criteria for checking the causality and stability of DTI and ETI systems based on their impulse response.

**Theorem 5** (a1) Consider a DTI system \(\Delta\) and let \(h = \Delta(q)\) be its impulse response. Then: (a1) The system is causal iff \(h(t) = \bot\) for all \(t < 0\). (a2) The system is BIBO upper-stable iff \(\bigvee_t h(t) < \top\).

(b) Consider an ETI system \(\mathcal{E}\) and let \(h' = \mathcal{E}(q')\) be its dual impulse response. Then: (b1) The system is causal iff \(h'(t) = \top\) for all \(t < 0\). (b2) The system is BIBO lower-stable iff \(\bigwedge_t h'(t) > \bot\).
Proof: Part (a): (a1) follows from the definition of causality since the output can be written as
\[ \Delta(u)(t) = \bigvee_{k} u(t-k) \star h(k) \]. (a2) Sufficiency: If \( u \) and \( h \) have suprema \( < \top \), then their dilation \( y = u \bigodot h \) also has a supremum \( < \top \) because
\[ y(t) \leq \bigvee_{k} u(k) \bigstar \bigvee_{k} h(k), \quad \forall t \]

Necessity: Assume now that \( \Delta \) is upper-stable. Then \( \bigvee_{t} h(t) \) must be \( < \top \), because otherwise we can find a bounded input yielding an unbounded output. For example, the input \( u(t) = q(t) \) yields as output \( y(t) = h(t) \). Obviously, this \( u \) is bounded, but if \( \bigvee_{t} h(t) = \top \) we get an unbounded output. Part (b) follows by duality.

The stability of a linear dynamical system can be expressed via the eigenvalues of its state transition matrix \( A \). For max-\( \star \) (min-\( \cdot \)) systems we derive below a conceptually similar result that links the upper (lower) stability of the system with the (dual) principal eigenvalue of \( A \).

**Theorem 6** (a) Consider a max-\( \star \) system whose matrices do not contain any \( \top \) elements. If \( \lambda(A) \leq e \), the system is upper-stable. (b) If a min-\( \cdot \) system has matrices without any \( \bot \) elements and \( \lambda(A) \geq e' \), then the system is lower-stable.

Proof: (a) By (69), if \( C = [c_i] \) and \( B = [b_j]^T \),
\[ h(t) = \max_i \max_j c_i \bigstar a_{ij}^{(t)} \bigstar b_j \quad (86) \]
where \( a_{ij}^{(t)} \) is the \( i,j \) element of matrix \( A^{(t)} \). By Lemma [2] we have \( A^{(t)} \leq \Gamma(A) = [\gamma_{ij}] \), and equivalently \( a_{ij}^{(t)} \leq \gamma_{ij} \leq \top \) for all \( i,j,t \geq 1 \). Thus,
\[ \bigvee_{t} h(t) \leq \max_{i,j} \gamma_{ij} \bigstar \max_i c_i \bigstar \max_j b_j \leq \top \quad (87) \]
Hence, by Theorem 5 the system is BIBO upper-stable. This upper bounds the null-state response \( y_{ns}(t) \) of the output. Now if \( x(0) \neq \bot \), the null-input response \( y_{ni}(t) = C \bigodot A^{(t)} \bigodot x(0) \) will also be upper bounded via a similar proof as above. Thus, the system is upper-stable. Part (b) follows by duality.

From another viewpoint, the useful information in a signal \( f(t) \) analyzed by a DTI system exists only at times where \( f(t) \) is not null. Thus, its support (or effective domain) is defined by \( \text{Spt}_\vee(f) \triangleq \{ t : f(t) > \bot \} \). An alternative useful bound for signals \( f(t) \) processed by such systems is their supremal ‘absolute value’ over their support:
\[ M_f \triangleq \bigvee_{t \in \text{Spt}_\vee(f)} \mu(f(t)) \quad (88) \]
where \( \mu(a) \triangleq a \vee \overline{a} \) is called the absolute value seminorm in [18] and is ‘sublinear’ over a self-conjugate clodum in the sense that \( \mu(a \vee b) \leq \mu(a) \vee \mu(b) \). We call max-\( \star \) systems BIBO absolutely stable iff a bounded input yields a bounded output in the following sense:
\[ M_u < \top \implies M_y < \top \quad (89) \]
This is controlled by the system’s impulse response as shown next.

**Theorem 7** Consider a DTI system \( \Delta \) over a self-conjugate clodum whose matrices do not contain any \( \top \) elements. Let \( h = \Delta(q) \) be its impulse response. Then, the system is BIBO absolutely stable iff \( M_h < \top \).
Further, the absence of \( \Delta \) may be only a subset of dimensional anomalies in minimax algebra \([18]\), there is no guarantee of exact solution even when \( M_h \) may not be the same with the row rank. Thus, by using \( M_h \), we can rewrite the above as

\[
\mu(y(t)) \leq \bigvee_{k \in U \cap \langle H^* \rangle_{+t}} \mu[u(k) \ast h(t - k)] \leq M_u \ast M_h
\]

for all \( t \) in the Minkowski set addition \( U \oplus H = \{ k + \ell : k \in U, \ell \in H \} \) of the two supports, where \( (H^*)_{+t} \) denotes the reflected \( H \) translated by \( t \). Necessity: Assume that \( \Delta \) is stable. Then \( M_h \) must be finite, because otherwise we can find a bounded input yielding an unbounded output. For example, the bounded input \( u(t) = q(t) \) yields the output \( y(t) = h(t) \) which is unbounded if \( M_h = \top \).

The next theorem links absolute stability with the principal eigenvalue of the system.

**Theorem 8** Consider a max\( \ast \) system over a clog whose matrices do not contain any \( \top \) elements. For matrix \( A = [a_{ij}] \) assume that it is irreducible, \( a_{ii} > \perp \) for some \( i \), and there is a unique critical cycle of length \( d \) corresponding to its finite principal eigenvalue \( \lambda(A) \). Then: (a) If \( \lambda(A) = e \), the impulse response of the system is eventually periodic with period \( d \). (b) The system is BIBO absolutely stable iff \( \lambda(A) = e \).

**Proof:** (a) As shown for the max-plus case in \([16]\) under the above hypotheses for \( A \), if \( \lambda(A) = 0 \), then \( A \) is order-\( d \)-periodical, i.e. there is an integer \( k_0 \) such that \( A^{(k+d)} = A^k \forall k \geq k_0 \). The proof of the above in \([16]\) can be extended to general clogs. Hence, by \([18]\), there exists \( k_0 \) such that \( h(k+d) = h(k) \) for all \( k \geq k_0 \). (b) Let \( \lambda = \lambda(A) \). Then \( \lambda \ast A \) is order-\( d \)-periodical and hence \( A^{(k+d)} = \lambda^{\ast d} \ast A^k \) for all \( k \geq k_0 \).

Further, the absence of \( \top \) values in the system’s matrices guarantees that \( h(k) \) does not have any such values. Now, if \( \lambda = e \), then \( h(k+d) = h(k) \forall k \geq k_0 \) and hence \( M_h < \top \). In contrast, if \( \lambda \neq e \), then \([18]\) will drive asymptotically (as \( k \to \infty \)) the values of \( \mu(h(k)) \) unbounded, and hence \( M_h = \top \).

Q.E.D.

**8 Reachability, Observability**

Assume single-input single-output systems with constant matrices described by \([65]\), acting on a CWL over a cludum \( K \). A max\( \ast \) system is called reachable in \( k \)-steps if the following system of nonlinear equations can be solved and provide the control input sequence \( u_k = [u(1),...,u(k)]^T \) required to drive the system from the initial state \( x(0) \) to any desired state \( x(k) \) in \( k \) steps:

\[
x(k) = A^{(k)} \oplus x(0) \lor C_k \oplus u_k
\]

where \( C_k = [A^{(k-1)} \oplus B, \cdots, A \oplus B, B] \) is called the controllability matrix. This system of max\( \ast \) equations can be solved using the methods of Sec. 5. However, we can simplify it first by assuming that the input is dominating the initial conditions (e.g. by assuming inputs with sufficiently large values); then, the second term is greater than the first term of the right hand side, and we can rewrite the above as

\[
C_k \oplus u_k = x(k)
\]

If there is an exact solution to \([22]\), the system is called weakly-reachable \([22]\). Because of some dimensional anomalies in minimax algebra \([18]\), there is no guarantee of exact solution even when \( C_k \) has full column rank (i.e. \( n \) max\( \ast \) independent columns) because the max\( \ast \) span of its columns may be only a subset of \( \mathbb{R}^n \), unlike the linear system case where full rank of \( C_k \) makes the system reachable in at most \( k = n \) steps. Another difference with linear systems is that the max\( \ast \) column rank may not be the same with the row rank. Thus, by using \( k > n \) one may obtain a matrix \( C_k \)
that will give an exact solution. By Theor. 4, if there exists an exact solution, the greatest solution is the lattice erosion

$$\hat{u}_k = \varepsilon(x(k)) = C_k^T \Box'_\chi x(k)$$  \hfill (93)

where $\varepsilon$ is the adjoint erosion of the dilation $\delta(y) = C \ominus y$. (See Sec 3.3.) If $K$ is a clog, the solution (93) becomes

$$\hat{u}_k = C_k^* \Box'_{x'} x(k)$$  \hfill (94)

However, in certain applications Eq. (92) may be too strong of a condition and it may be sufficient to solve an approximate reachability problem that has some optimality aspects. Specifically, consider finding an optimal control input sequence $u_k$ as solution to the following constrained optimization problem:

$$\text{Min } \| C_k \Box u_k - x(k) \| \text{ s.t. } C_k \Box u_k \leq x(k)$$  \hfill (95)

where the norm $\| \cdot \|$ is either the $\ell_\infty$ or the $\ell_1$ norm. Then the optimal solution is (93) or (94).

The above ideas can also be applied to the observability problem. A max-$\star$ system is observable if we can estimate the initial state by observing a sequence of output values. By (65), this can be done if the following system of nonlinear equations can be solved:

$$\begin{bmatrix} y(1) \\ \vdots \\ y(k) \end{bmatrix} = \begin{bmatrix} C \Box A \\ \vdots \\ C \Box A^{(k)} \end{bmatrix} \Box_{x(0)} \vee \begin{bmatrix} y_{ns}(1) \\ \vdots \\ y_{ns}(k) \end{bmatrix}$$  \hfill (96)

Assuming that the first term of the right hand side containing the initial state dominates the second term that contains the input (e.g. by assuming inputs with sufficiently small values), we can rewrite the above as

$$O_k \Box x(0) = y_k = [y(1), ..., y(k)]^T$$  \hfill (97)

This equation can be solved exactly or approximately by using the same methods as for the reachability equation. Thus, if $K$ is a clog, the general solution is

$$\dot{x}(0) = O_k^* \Box' y_k$$  \hfill (98)

and has the property that it is the largest solution with $O_k \Box \dot{x}(0) \leq y_k$.

9 Applications, Special Cases

9.1 Max-Sum systems

One broad class of nonlinear dynamical systems is described by (2) or (6) by using $K = \mathbb{R}$ as the set of scalars, the standard addition $+$ (extended over $\mathbb{R}$) as the scalar ‘multiplication’ $\star$, and the following max-sum $\boxplus$ and min-sum $\boxplus'$ matrix products as the general matrix ‘product’ and its dual, respectively:

$$C = A \boxplus B \quad , \quad c_{ij} = \bigvee_{k=1}^n a_{ik} + b_{kj}$$  \hfill (99)

$$C = A \boxplus' B \quad , \quad c_{ij} = \bigwedge_{k=1}^n a_{ik} + ' b_{kj}$$  \hfill (100)

where $+$ and $+$' are identical for finite reals, but $a + (-\infty) = -\infty$ and $a + ' (+\infty) = +\infty$ for all $a \in \mathbb{R}$. Henceforth, we shall use the same symbol $+$ for both scalar operations. The max-plus clog $(\mathbb{R}, \vee, \wedge, +)$ and the above nonlinear matrix products are the basis of minimax algebra [18]. Special cases of max/min-plus dynamical systems have been used for modeling, control and
optimization problems in (i) discrete event dynamical systems (DES) for applications including scheduling, manufacturing and transportation, (ii) shortest path and related dynamic programming problems, and (iii) operations research; see [2, 14, 17, 15, 16, 17, 19, 22, 28, 29] and the references therein.

Next, we examine state-space formulations and stability issues for two classes of max-sum dynamical systems modeling recursive nonlinear filtering and shortest path computation, which can be described by generalized versions of the max-plus recursion (8) or its dual.

9.1.1 State-Space Models of Recursive Nonlinear Filters

A very large class of discrete linear time-invariant systems used in control and signal processing [13, 40] is modeled via the following class of linear difference equations:

$$y(t) = \sum_{i=1}^{n} a_i y(t-i) + \sum_{j=0}^{m} b_j u(t-j)$$  \hspace{1cm} (101)

Replacing sum with maximum and multiplication with addition gives us the following nonlinear max-sum difference equation [32]

$$y(t) = \left( \bigvee_{i=1}^{n} a_i + y(t-i) \right) \lor \left( \bigvee_{j=0}^{m} b_j + u(t-j) \right)$$  \hspace{1cm} (102)

The signal values and all coefficients $a_i, b_j$ are from the clog $\mathbb{R}$. If some $a_i = -\infty$, the term with $y(t-i)$ is not used in the equation. Special cases of such nonlinear difference equations have found many applications in morphological signal and image processing [37, 34, 45, 23], convex analysis [31, 44], and optimization [3, 4].

The max-plus version of the general state equations (2) can also model the dynamics of recursive discrete-time filters described by the above max-sum difference equation. Specifically, if $m = 0$, setting $x_i(k) = y(k-n+i-1)$, $i = 1, \ldots, n$, and choosing matrices

$$A = \begin{bmatrix} -\infty & 0 & -\infty & \ldots & -\infty \\ -\infty & -\infty & 0 & \ldots & -\infty \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -\infty & -\infty & -\infty & \ldots & 0 \\ a_n & a_{n-1} & a_{n-2} & \ldots & a_1 \end{bmatrix}, \quad B = [b_0]$$

$$C = \begin{bmatrix} a_n, \ldots, a_1 \end{bmatrix}, \quad D = [b_0]$$  \hspace{1cm} (103)

models (102) as a max-plus special case of (2).

Consider now the following min-sum difference equation, which describes a dual system to that of (102):

$$y(t) = \left( \bigwedge_{i=1}^{n} a_i + y(t-i) \right) \land \left( \bigwedge_{j=0}^{m} b_j + u(t-j) \right)$$  \hspace{1cm} (104)

Its dynamics can be modeled by the min-sum version of the general state equations (6). It admits a state space model as in (103), the only difference being that the null elements in the system matrices should be $+\infty$.

The system described by (102) or (103) is a dilation time-invariant (DTI) system iff all its initial conditions are null ($-\infty$) and is initially at rest, i.e. if $u(t) = -\infty$ for $t \leq t_0$ then $y(t) = -\infty$ for $t \leq t_0$. Similar conditions apply for (104) to make it correspond to an erosion time-invariant (ETI) system.

**Theorem 9** The max-plus principal eigenvalue of the matrix $A$ in (103) is equal to $\lambda(A) = \sqrt[n]{a_k/k}$. 
Proof: The directed weighted graph of $A$ has $n$ nodes and $n$ elementary cycles $(j, j + 1, ..., n, j)$ for $j = 1, ..., n$, each with average weight $a_{n-j+1}/(n-j+1)$. Hence, $\lambda(A) = \sqrt[n]{a_k/k}$. Q.E.D.

Thus, the max-sum system corresponding to the recursive nonlinear filter described by (102) is upper stable iff all the coefficients $a_k$ are non-positive and absolutely stable if at least one of them is zero. Such a numerical example is shown in Fig. 2(a), where Theorem 8 also applies and predicts a periodic impulse response. Further, responses from stable and unstable DTI and ETI systems are shown in Fig. 2. The stable outputs of Figs. 2(c,d) illustrate the applicability of recursive DTI (ETI) for upper (lower) envelope detection, as explored in [32].

![Figure 2: Responses of DTI or ETI systems described by the recursive max-plus equation (102) or its min-plus version (104); in all cases $m = 0$, $b_0 = 0$. (a) Upper impulse response (first 50 samples) of a $n = 10^{th}$-order DTI system for two coefficient sequences $\{a_k\}$: in solid line $a_k = -\sin(\pi k/10)/10$, $k = 1, .., 10$, whereas in dash line $a'_k = (|k-5| - 5)/50$ for $k = 1, .., 9$ and $a'_{10} = 0.1$. (b) Lower impulse response (first 50 samples) of a $10^{th}$-order recursive ETI system for two coefficient sequences: in solid line $a_k = \sin(\pi k/10)/10$, whereas in dash line $a'_k = (5 - |k - 5|)/50$, $k = 1, .., 10$. (c) Output signals from two DTI systems for an AM input signal (dashed line). The first output (solid line) is from the stable system $y(t) = \max[y(t-1) + a_1, u(t)]$ with $a_1 = -0.008$. The second output (dotted line) is from the unstable system that generated the unstable impulse response of (a). (d) Input signal as in (c) and output from the min-plus system $y(t) = \min[y(t-1) - a_1, u(t)]$.](image-url)

9.1.2 Dynamic Programming

The max-plus or min-plus recursive equations can also express various forms of dynamic programming, either of maximizing some gain or minimizing some cost or distance [5, 2]. For example consider (8) and assume that $a_{ij}$ is the transition gain from state $i$ to state $j$ between two consecutive time instants and that $x_i(t)$ represents the maximum possible gain to reach state $i$ in $t$ steps starting from some initial state at $t = 0$. Then (8) with a transposed transition matrix, i.e. the max-sum system

$$x(t) = A^T \boxplus x(t-1), \quad x(0) = [0, -\infty, ..., -\infty]^T,$$

models a dynamic programming algorithm where, starting from state 1 with zero gain, we move from state to state aiming at solving the above optimization problem by sequentially maximizing the gain. The optimum path can be found by backtracking.
9.1.3 Distance maps and min-plus recursions

The min-plus version of $\mathbb{S}$ models shortest path problems. Given a 2D rectangular field $f : \mathcal{V} \to \mathbb{R}$ on a grid $\mathcal{V}$ of $M \times N$ pixels, its weighted distance transform is defined by

$$D_f(i,j) = \bigwedge_{(k,\ell) \in \mathcal{V}} d(i-k,j-\ell) + f(k,\ell)$$

(106)

where $d(\cdot)$ is Euclidean distance. For various cases of $f$, the above distance computation problem is at the heart of several well-known optimization problems [21]. If $D_f$ is available, we can solve the shortest path problem from any point by following the gradient of the distance map. If $f$ equals $q_S$, which is the lower indicator function of a set $S \subseteq \mathcal{V}$ with values 0 on $S$ and $+\infty$ on $\mathcal{V} \setminus S$, then $D_f$ becomes the distance transform of the set $S$:

$$D_S[i,j] = \min_{(k,\ell) \in S} \|i-k,j-\ell\|$$

(107)

which measures distances from $S$ out into its containing field. Consider indexing rowwise the 2D rectangular grid $\mathcal{V}$ of $M \times N$ pixels $(i,j)$ as a 1D sequence of points $t = N(i-1)+j$, $i = 1, ..., M$, $j = 1, ..., N$. A good approximation to the Euclidean distance function $D_S(t)$ is to compute the chamfer distance $[10]$ by propagating a $3 \times 3$ mask (8-pixel neighborhood) of local distance steps $(a,b)$. A serial implementation is an iterative algorithm where the 8-pixel neighborhood is partitioned into two 4-pixel subneighborhoods, and each new array of results sequentially passes through recursive infimal convolutions $y_i(t)$, $i = 1, 2, 3, ..., $ which for odd $i$ are a forward pass with the submask of Fig. 3(a) scanning rowwise the 2D field from top to bottom and for even $i$ are a backward pass with the reflected submask in the reverse scanning order. The $i$-th forward pass is described by the min-plus difference equation

$$y_i(t) = \bigwedge_{k=1}^{N+1} w_k + y_i(t-N+k-2) \land u_{i-1}(t)$$

(108)

where $w_1 = b, w_2 = a, w_3 = b, w_{N+1} = a$ and all other $w_k$ are $+\infty$, $u_0 = q'_S$ and $u_i = y_i$ for $i \geq 1$.

Its dynamics can be modeled by the min-sum version of the general state equations [6]. It admits a state space model as in [103] with $n = N+1$ states $x_k(t) = y(t-N+k-2)$, the only differences being that the null elements ($-\infty$) in the sparse system matrices should be replaced with $+\infty$, and all elements in the last row of $A$ and in $C$ are $+\infty$ except at four positions ($k = 1, 2, 3, N+1$) where they are equal to the corresponding local distances. The source set $S$ could be a small region from which we propagate distances; see Fig. 3(b,c). If the field contains impenetrable obstacles (like ‘walls’) $W$, distance maps can be produced that account for this impenetrability, and then shortest paths can be found that avoid collision with the walls, which is useful in robotics [10]. This can be done by imposing in each iteration values $+\infty$ at all points of the wall in the inputs $u$. The algorithm [103] generally converges to $D_S[t] = \lim y_i(t)$, and the number of required passes is two if there are no obstacles; see Fig. 3(d). For a 1D sequence $S$ of points, we need only two passes as the following example illustrates with recursions $y_1(t) = \min[y_1(t-1)+1,u_0(t)]$ and $y_2(t) = \min[y_2(t+1)+1,y_1(t)]$:

| $u_0$ | $\infty$ | 0 | $\infty$ | $\infty$ | 0 | $\infty$ | $\infty$ | $\infty$ | 0 |
|-------|-----------|---|-----------|-----------|---|-----------|-----------|-----------|---|
| $y_1$ | $\infty$ | 0 | 1 | 2 | 3 | 0 | 1 | 2 | 3 |
| $y_2$ | 1 | 0 | 1 | 2 | 1 | 0 | 1 | 2 | 3 | 2 | 1 | 0 |

Note that both recursive equations are stable min-plus systems.

9.2 Max-Product systems

Another class of nonlinear dynamical systems is obtained by using the nonnegative numbers $K = [0, +\infty]$ as scalars, the standard product ($\times$) as scalar ‘multiplication’, and the following max-
Figure 3: (a) Coefficient submask for forward pass of sequential distance transform. (b) Source set \( S \) and the obstacle wall set \( W \). (c) First (forward) pass of constrained distance transform with steps \((a, b) = (24, 34)/25\). (d) Fourth (backward) pass and final result.

The scalar multiplications \( \times \) and \( \times' \) coincide over \((0, +\infty)\), but \( a \times 0 = 0 \) and \( a \times' (+\infty) = +\infty \) for all \( a \in [0, +\infty] \). Henceforth, we shall use the same symbol \( \times \) for both scalar operations. Here the scalar arithmetic is based on the max-times \( \sqcup \), \( \sqcap \), \( \land \), \( \times \). This max-product formalism can model dynamical systems whose inputs, states, and outputs are constrained to be nonnegative. Note that there is an isomorphism between the max-sum and the max-product systems because, if we have the following max-product state equations

\[
x(t) = A \boxtimes x(t - 1) \lor B \boxtimes u(t)
\]

and take logarithms of both sides element-wise, we obtain the max-sum equations

\[
\log x(t) = \log A \boxplus \log x(t - 1) \lor \log B \boxplus \log u(t)
\]

Such systems have found applications in speech recognition and other natural language processing tasks using finite-state automata \([39, 25]\), in computer vision \([21]\), and the max-product algorithm in belief propagation \([41]\) and related probabilistic graphical models used in machine learning \([7]\).

### 9.2.1 Viterbi Algorithm and HMMs

Given a time sequence of observations (feature vectors) \( O = (o_t)_{t=0}^T \), a fundamental problem in their statistical modeling using hidden Markov models (HMMs) \([12]\) with \( n \) discrete states \( \{1, ..., n\} \) is to find the best sequence of states \( \hat{s} = (s_0, s_1, ..., s_T) \) that maximizes the probability \( \Pr(O, \hat{s} | \theta) \), where \( \theta = ([\pi_i], [a_{ij}], [p_i]) \) are the HMM parameters: \( \pi_i \) are the initial state probabilities at \( t = 0 \), \( a_{ij} = \Pr(s_t = j | s_{t-1} = i) \) are state transition probabilities, and \( p_i(t) \) are the state-conditional observation probabilities \( p(o_t | s_t = i) \) often modeled by Gaussian Mixture models (GMMs). Consider the highest probability of a single partial state sequence ending at state \( i \) at time \( t \) and accounting for the first \( t + 1 \) observations:

\[
x_i(t) = \max_{s_0, ..., s_{t-1}} \Pr[s_0, ..., s_{t-1}, s_t = i, o_0, ..., o_t | \theta]
\]

One solution is to use the Viterbi algorithm to find the max global score

\[
\hat{P} = \Pr(O, \hat{s} | \theta) = \max_i x_i(T)
\]
and then find the optimal state sequence via backtracking. This is essentially dynamic programming
and amounts to evolving the following system for \( t = 1, \ldots, T \)

\[
\begin{align*}
  x_i(t) &= \left( \bigvee_{j=1}^n a_{ji} x_j(t-1) \right) \cdot p_i(t) \\
  y(t) &= \bigvee_{i=1}^n x_i(t)
\end{align*}
\]  

(115)

with \( x_i(0) = \pi_i p_i(0) \). Then, this is a max-product system with matrices \( A(t) = [a_{ji}]p_i(t) \), \( C = [1,1,\ldots,1] \) and zero input. The Viterbi score is given by the final output \( \hat{y} = y(T) \).

### 9.2.2 Attention Control and Multimodal Saliencies

Assume a video sequence of audio-visual (AV) events each to be scored with some degree of saliency in \([0, 1]\) where ‘saliency’ is some bottom-up low-level sensory form of attention by a human watching this video. The states \( x_1, x_2, x_3, x_4 \) represent time-evolving mono- or multi-modal saliencies, where \( 1=\text{audio}, 2=\text{visual}, 3=\text{audio-visual}, \) and \( 4=\text{non-salient} \). Peaks in these saliency trajectories signify important events, which can be automatically detected and produce video summaries that agree well with human attention [20]. The following state equations are a possible max-product dynamical model we have proposed for the evolution of these saliency states [36]:

\[
  x_i(t) = \left( \bigvee_{j=1}^4 a_{ji} x_j(t-1) \right) \cdot p_i(t) \lor \left( \bigvee_{j=1}^4 b_{ij} u_j(t) \right)
\]

(116)

for state \( i = 1, 2, 3, 4 \). The constants \( a_{ij} \) represent state transition probabilities and \( p_i(t) = p(\mathbf{o}_t | s_t = i) \) denote the probabilities of observed low-level feature vectors \( \mathbf{o}_t \) while being at the \( i \)-th saliency state. We assume that the parameters \( a_{ij}, b_{ij} \) and \( p_i(t) \) are given.

Given a time sequence of such observations (\( \mathbf{o}_t \)) one can fit HMMs to these data using maximum likelihood. Then, the first term in the RHS of (116) models the evolution of the Viterbi dynamic programming algorithm [115] used in HMMs. For example, if the inputs \( u_i(t) \) are all null, then the single output \( y(t) = \bigvee_i x_i(t) \) computes the Viterbi score [114]. One main difference of our system [116] with the Viterbi algorithm [115] is that we have the probability-like signals \( u_i(t) \) which can act as control inputs coming possibly from previous human attention states or higher-level events; e.g. detected human faces, voice activity, or text semantics. Another difference is that the outputs of the dynamical system can be various min-max combinations of the saliency states of various modalities; e.g. the single output

\[
  y(t) = c_1 x_1(t) \lor c_2 x_2(t) \lor d_1 u_1(t) \lor d_2 u_2(t)
\]

(117)

forms a weighted max-product fusion of the audio and visual saliencies as well as the two corresponding inputs. In such modality and input combinations, the max rule can be replaced by min too. A third difference is that the data-controlled probabilities \( p_i(t) \) can enter not only via multiplication but also via any commutative binary operation \( \star \) that distributes over maximum. If \( \star = \max \), then the \( p_i(t) \) can be viewed as control inputs. Finally, our CWL theoretical formulation allows us to also compute analytically the responses of such max-product dynamical systems; see Sec. 4.

In our experiments [36] we estimated the state transition probabilities \( a_{ij} \) using the EM algorithm on some training data from movie videos. For estimating the observation data probabilities \( p_i(t) \) we fitted GMMs to audio and visual feature vectors extracted from the video data at each frame \( t \). Figure 4 shows the results (on testing data from the same movie videos) of various approaches we have initiated to track the joint audio-visual (AV) saliency state and compare it (i) with human annotations, i.e. binary AV saliency manually annotated by a human who observed these movie videos, and (ii) with an AV saliency automatically computed in [20] by fusing saliencies of the audio and visual streams measured from monomodal cues. Our ongoing research goal here is to develop a computational model that can track human attention in the form of audio-visual saliency.
states based on multimodal sensory inputs. As shown in Fig. 4 and explained numerically in [36], our results using the max-product dynamical system are encouraging; they can track audio-visual saliencies with smaller error than bottom-up feature-based local measurements and can improve with higher-level control input.

Figure 4: Evolution of audio (blue), visual (red) and audio-visual (green) bottom-up likelihoods computed from observed features. We also see the human annotations and the 3-Best state paths using the max-product dynamical system (116) with \( \star \) being product operation and two control inputs \( u_1(t) \) and \( u_2(t) \) providing binary information from voice and face detection respectively. (This figure is best viewed in color.)

9.3 Max-T-norm systems and Fuzzy Markov Chains

There are many types of nonlinear dynamical systems where the elements of the state, input and output vectors represent probabilities or memberships. Examples include probabilistic or fuzzy control systems [1, 30, 38], fuzzy image convolutions [8, 33], as well as certain types of neural nets with max-min combinations of inputs [26, 30, 48]. The dynamics of large classes of such systems can be described by the general model if we restrict the set of scalars to be \( \mathbb{K} = [0,1] \) and use as scalar ‘multiplication’ \( a \star b = T(a,b) \) a fuzzy intersection norm [30], i.e., a binary operation \( T : [0,1]^2 \rightarrow [0,1] \) that is i) commutative, ii) associative, iii) increasing and iv) satisfies the boundary condition \( T(a,1) = a \) for all \( a \in [0,1] \). This is also known as ‘triangular norm’ (t-norm) in statistics. We also require that \( T \) is continuous, which makes it a scalar dilation [38]. As ‘dual scalar multiplication’, we use a continuous binary operation \( S(a,b) = a \star' b \) that satisfies (i)-(iii) and the dual boundary condition \( S(a,0) = a \). This is a fuzzy union norm [30], also known as ‘t-conorm’, and is a scalar erosion on \([0,1]\). Choosing in the general lattice dynamical model the above set of scalars and ‘multiplications’ among them creates the case of max-T-norm and min-Snorn systems, obtained by replacing in (2) and (6) the general max-\( \star \) matrix product and its dual with the following versions:

\[
C = A \boxtimes B , \quad c_{ij} = \bigvee_{k=1}^{n} T(a_{ik}, b_{kj}) \tag{118}
\]

\[
C = A \boxtimes' B , \quad c_{ij} = \bigwedge_{k=1}^{n} S(a_{ik}, b_{kj}) \tag{119}
\]
Usually we select $S(a, b) = a \star b = T'(a, b) = 1 - T(1 - a, 1 - b)$; then $(S, T)$ form a negation duality, but not an adjunction. The most well-studied choice for the $T$ norm and its dual norm $S$ are the min and max operations, respectively. Another known case is for $T$ to equal the product operation. Table 2 shows these cases and their adjoints so that $(\zeta, T)$ and $(S, \eta)$ are scalar adjunctions. There are also numerous other choices.

Table 2: T-norms, Conorms and their Adjoints

| $T(a, v)$ | $\zeta(a, w)$ | $S(a, w)$ | $\eta(a, v)$ |
|-----------|---------------|-----------|--------------|
| $\min(a, v)$ | $\max(\lfloor w > a \rfloor, w)^\dagger$ | $\max(a, w)$ | $\min(\lfloor v > a \rfloor, v)$ |
| $a \cdot v$ | $\min(w/a, 1)$ | $a + w - a \cdot w$ | $\max(w/a, 0)$ |

$\dagger$ $[P]$ is the Iverson bracket with value 1 (0) if $P$ is true (false).

An application of the above ideas to state-space description and control of fuzzy dynamical systems is presented in [35]. Further, dynamical systems with states $x(t) \in [0, 1]^n$ and transition rule based on the max-min matrix multiplication ($\star = \min$)

$$x(t + 1) = A \boxtimes x(t) = A^{(t)} \boxtimes x(0), \quad A = P^T$$

where $P = [p_{ij}] \in [0, 1]^{n\times n}$ is the matrix of state transition probabilities or fuzzy relations among states $(i, j)$, have been called fuzzy Markov chains (FMCs) in [1] and studied for decision-making. An advantage they have over classical Markov chains (whose transition rule is based on the sum-product matrix multiplication) is that the powers of the transition matrix always reach a stationary solution $x(\infty)$ in a finite number of steps. Namely, the max-min powers of any matrix $A$ either converge in a finite time $\tau$, i.e. $A^{(\tau + 1)} = A^{(\tau)}$, or oscillate with a finite period $\nu$ after some finite power $\tau$. In the aperiodic case ($\nu = 1$), if the limiting matrix $A^{(\tau)}$ has identical columns, then the stationary solution $x(\infty)$ is independent of the initial state $x(0)$ and the FMC is called ergodic.

We can extend these results for more general FMCs by using alternative $T$-norms, e.g. the product. In particular, for both cases of Table 2 (i.e. when $T$ is the minimum or product operation on $[0, 1]$) it can be shown by repeating the proof of Lemma 2 (and without the restriction that $a_{ij} < 1 = e = T$) that (82) always holds. From this we can deduce the finite convergence properties of generalized FMCs. Further, if $a_{ii} = 1$ for all $i$, then it follows that $A^{(t)} \leq A^{(t+1)}$ for all $t \geq 1$; hence from (82) we can prove an aperiodic finite convergence since

$$\Gamma(A) = A^{(n)} = A^{(t)} \quad \forall t > n$$

Thus, $A \boxtimes \Gamma(A) = \Gamma(A)$. This implies that all columns of the metric matrix $\Gamma(A)$ are solutions of

$$A \boxtimes x = x$$

Such vectors are max-$T$ eigenvectors of $A$ whose principal eigenvalue is $\lambda(A) = 1$ and provide stationary solutions of the FMC. As a numerical example, consider the transition matrix $A$ and its powers of a max-min FMC:

$$A = \begin{bmatrix} 1 & 0.4 & 0 \\ 0.3 & 1 & 0.5 \\ 0.7 & 0.2 & 1 \end{bmatrix} \leq A^{(2)} = A^{(3)} = \Gamma(A) = \begin{bmatrix} 1 & 0.4 & 0.4 \\ 0.5 & 1 & 0.5 \\ 0.7 & 0.4 & 1 \end{bmatrix}$$

The columns of $\Gamma(A)$ provide stationary solutions of this FMC; e.g. $A \boxtimes [1, 0.5, 0.7]^T = [1, 0.5, 0.7]^T$.

10 Conclusions

In this work we have developed a unified theory of nonlinear dynamical systems of the max-$\star$ type and their dual min-$\star'$ type over nonlinear vector and signal spaces which we call complete
weighted lattices (CWLs). Special cases include max-plus systems encountered in discrete event scheduling and automated manufacturing, max-product systems like the Viterbi algorithm, and the max-fuzzy-norms systems encountered in certain types of neural nets and fuzzy control. We have studied several control-theoretic and signal processing aspects of such systems, both by using CWLs for shorter proofs of known cases and by extending the theory to more general cases. Further we have also outlined several application areas that are either new or not often encountered in the literature, which has emphasized so far the max-plus case and its application to discrete events systems; examples include state-space representation and stability analysis of geometric filtering, distance maps, fuzzy Markov chains, a generalized Viterbi algorithm for HMMs with control inputs and its application to tracking salient events in multimodal videos.

Overall, the unified formulation of the above systems and the corresponding CWL framework provide several advantages over minimax algebra which include: capability of handling both finite- and infinite-dimensional cases; co-existence over the same space of the max- and the dual min- systems; lattice monotone operators that can represent both matrix-vector multiplications in state-space as well as sup/inf input-output signal convolutions; lattice adjunctions (pairs of dual operators) that yield optimal solutions to max- and min- equations via lattice projections.

Our ongoing and future work in this area focuses on the following directions:

- Develop efficient approaches for estimating the max- system parameters and state from observed data.
- Further study the max-product dynamical systems and their relationship with Markov chains.
- Attention control from multimodal sensory data and integration with high-level semantic events via feedback.
