Radiative symmetry breaking is a well known phenomenon in perturbation theory. We study the problem in a non-perturbative framework, i.e. lattice simulations. The example of the bosonic sector of the SU(2)-Higgs model is considered. We determine the minimal scalar mass which turns out to be higher than the mass value given by 1-loop continuum perturbation theory.

1. INTRODUCTION

Symmetry breaking is a fundamental concept in particle physics. The most popular mechanism is the Higgs mechanism. Also radiative symmetry breaking (Coleman-Weinberg (CW) mechanism [1]) is well known. The CW mass is obtained when the tree level mass parameter is zero, i.e. the Higgs mass is induced by radiative corrections. The value of the CW mass is near to the smallest possible Higgs mass.

Connected to the CW mechanism is the problem of vacuum stability, i.e. the value of the minimal Higgs mass e.g. in the Standard Model. Clearly the latter problem would be more interesting to study in a non-perturbative framework. However, putting a chiral top quark on the lattice is difficult, therefore in this contribution we study symmetry breaking on the lattice only in the bosonic sector of the SU(2)-Higgs model. Still this is a difficult two scale problem, since the CW mass is an order of magnitude smaller than the W mass.

2. LATTICE FORMULATION

The lattice action in standard notation is:

$$S[U, \varphi] = \beta \sum_{pl} \left(1 - \frac{1}{2} \text{Tr} U_{pl}\right)$$

$$+ \sum_{x} \left\{ \frac{1}{2} \text{Tr} (\varphi_{x}^{+} \varphi_{x}) + \lambda \left[ \frac{1}{2} \text{Tr} (\varphi_{x}^{+} \varphi_{x}) - 1 \right]^{2} - \kappa \sum_{\mu=1}^{4} \text{Tr} (\varphi_{x+\mu}^{+} U_{x,\mu} \varphi_{x}) \right\}, \quad (1)$$

where $U_{x,\mu}$ denotes the SU(2) gauge link variable, $U_{pl}$ the path-ordered product of the four $U_{x,\mu}$ around a plaquette; $\varphi_{x}$ stands for the Higgs field. The continuum bare parameters are given: $g^{2} = 4/\beta$, $\lambda_{c} = \lambda/4/\kappa^{2}$, $\varphi_{c} = \sqrt{2\kappa/a\varphi}$ and $a^{2}m_{0}^{2} = (1 - 2\lambda)/\kappa - 8$. We choose $g^{2} = 0.5$, which gives renormalized gauge couplings close to the Standard Model value.

The CW mechanism is an inherently perturbative notion. Therefore, on the lattice we want to determine the smallest Higgs mass possible (which is not far from the CW mass). The lattice action is bounded from below for positive $\lambda$, while it is not for $\lambda < 0$. Thus $\lambda = 0$ is the interesting point relevant to the minimal and CW masses. Since the Higgs mass is a monotonous function of $\lambda/\kappa^{2}$, the limit $\lambda \to 0$ gives the smallest Higgs mass possible. Our aim is to determine the Higgs mass in this region and try to interpret the results in terms of the CW mechanism.

3. SIMULATIONS

The lattice simulation goes in the standard way as described e.g. in [4]. It is essential to simulate along a line of constant physics (LCP). For CW we define the LCP with $\lambda = 0$, $g_{R}^{2}$ fixed ($g_{R}$ is the renormalized gauge coupling, determined from a fit to the static potential) and the hopping parameter $\kappa$ tuned to the finite temperature phase transition point.

We simulate on $L_{t} \cdot L_{s}^{3}$ hot lattices ($L_{t} \ll L_{s}$) and perform an $L_{s} \to \infty$ extrapolation. Next we extrapolate to the continuum limit ($L_{t} \to \infty$). The physical lattice sizes for the various $L_{t}$’s are kept constant by choosing appropriate lattice ex-
Figure 1. Higgs mass squared as a function of $\lambda/\kappa^{2}_{cr}$. The masses corresponding to the three highest values of $\lambda/\kappa^{2}_{cr}$ are from [2,3], while the other points are new simulations.

In practice we take $\lambda$ very small ($5 \cdot 10^{-6}$, $2.875 \cdot 10^{-5}$, $5.25 \cdot 10^{-5}$) and fix $\beta = 8$. We found $\kappa_{cr}$ by constrained simulation, which is an appropriate method for strong phase transitions.

The physical scale is found for each $\lambda$, $\beta$, $\kappa_{cr}$ by performing simulations at $T=0$ and fixing $M_{W}=80 \text{ GeV}$. The quantity we extrapolate is $R_{HW} = M_{H}/M_{W}$.

Note that our LCP is not necessarily close to an LCP defined by the perturbative renormalization group running of $\lambda$ and $\beta$. In particular this is the case for the smallest $\lambda$ value given above.

4. RESULTS

In one loop perturbation theory one gets

$$M_{H}^{2} = v^{2} \cdot (8\lambda_{c} + 12B), \quad B = \frac{9g^{4}}{1024\pi^{2}}$$

The CW case corresponds to $\lambda_{c} = -B/2$. The minimal Higgs mass is for $\lambda_{c} = -B$.

Our results for the Higgs mass squared as a function of $\lambda/\kappa^{2}_{cr}$ are given in Fig. 1. It is convenient to plot the Higgs mass squared as a function of $\lambda/\kappa^{2}_{cr}$, since (at tree level) this is proportional to the continuum quartic coupling. Similar plots for higher Higgs masses have been presented in [4]. The straight line part of the curve on the right hand side of the figure obviously corresponds to the perturbative result. Even the slope is in reasonable agreement with the perturbative prediction. Clearly, for small values of $\lambda/\kappa^{2}_{cr}$ the straight line has to flatten out, since otherwise we would obtain negative Higgs mass squares. This is what is seen on the figure. It is easy to extrapolate to $\lambda/\kappa^{2}_{cr}=0$. We get $M_{H,min}^{2} = 115.78 \pm 4.95 \text{ GeV}^{2}$ to be compared to the perturbative value: $45.60 \text{ GeV}^{2}$ ($91.20 \text{ GeV}^{2}$) corresponding to the minimal Higgs mass (CW) cases. The lattice result is clearly much larger than the perturbative value.

One would expect that the perturbative and nonperturbative results are close to each other, since the quartic coupling is small in this region. However, it is clear that the LCP chosen brings in a true nonperturbative feature in the lattice calculation. The CW LCP is namely very far from the renormalization group LCP for small $\lambda$. Still, the large value of the smallest nonperturbative Higgs mass is a surprising result. We have carefully studied the finite size effects and believe that the discrepancy is caused most probably by the fact that our simulations are still far from the continuum limit.
