We investigate long time numerical simulations of the inviscid Rayleigh-Taylor instability at Atwood number one using a boundary integral method. We are able to attain the asymptotic behavior for the spikes predicted by Clavin & Williams\cite{15} for which we give a simplified demonstration. In particular we observe that the spike’s curvature evolves like $t^4$ while the overshoot in acceleration shows a good agreement with the suggested $1/t^5$ law. Moreover, we obtain consistent results for the prefactor coefficients of the asymptotic laws. Eventually we exhibit the self-similar behavior of the interface profile near the spike.

INTRODUCTION

The Rayleigh-Taylor (RT) instability appears when, under gravity, an heavy liquid is placed over a lighter one\cite{3}. This instability is crucial for our understanding of different phenomena in fluid mechanics: mixing, thermal convection (\cite{2} and cited ref. herein) and also finger number selection in splashes\cite{3}. It is also important in inertial confinement fusion where the mass ablation provides a stabilizing effect to the interface instability\cite{3}. Without ablation, after the exponential growth of the perturbations due to the linear RT instability, nonlinear profiles develop through the formation of bubbles of lighter fluid rising into the heavier one and falling spikes of the heavier liquid penetrating the lighter one. In the general situations of viscous fluids which are immiscible and/or have Atwood number not equal to unity ($A_T = (\rho_h - \rho_l)/(\rho_h + \rho_l)$ with $\rho_h$ and $\rho_l$ being the density of the heavier and lighter fluids respectively), famous mushrooms-like structures grow for larger times\cite{2, 7, 8}. The limit of an inviscid fluid above a vacuum ($A_T = 1$) without surface tension plays a specific role since no stabilizing effects are present in the linear dynamics. Numerous theoretical and numerical work have focused on this idealized limit in order to track insights into the instability itself\cite{2, 3, 8, 11, 12}. It has been shown using a conformal mapping that a finite time singularity might appear in the conformal plane\cite{12} and it is also suspected that for some sufficiently irregular initial conditions finite time singularities should also be observed in the physical plane. However, starting with sufficiently smooth initial conditions, the asymptotic dynamics\cite{11, 12} presents a constant velocity rising bubble separated by free falling tiny spikes as displayed on figure\cite{14} Although the rising bubble motion has been described using local properties of the flow\cite{14}, the asymptotic dynamics of the spikes is far from being well understood. The single mode approach gives a fair description of the constant velocity of the rising bubble ($v_0 = \sqrt{g/(3k)}$) where $g$ is the acceleration of the gravity and $k$ the wavenumber of the perturbation) but gives only partial results for the spike\cite{8}. The fluid there obeys free fall dynamics to a good approximation and the pressure field of the flow leads to an overshoot in the acceleration. The accelerated motion of the liquid stretches the spike geometry and one expects self-similar behaviour of the tip of the spikes. Recently,

![FIG. 1: Snapshots of the interface subject to the Rayleigh-Taylor instability for time ranging from $t = 0$ to $10$, starting with a small amplitude sine mode (left). On the right is shown the velocity of several points along the interface, non-dimensionalized with the stationnary bubble rising velocity $\sqrt{g/3k}$, as a function of time.](image)
sition, following the free fall $\frac{1}{2}gt^2$ at leading order, is shown to converge to the constant acceleration $g$ with an overshoot in acceleration decreasing like $t^{-5}$. In this letter, we present a numerical study of the Rayleigh-Taylor instability which focuses on the large time dynamics of the spikes in order to investigate the self similar dynamics predicted in [13]. We consider the dynamics for an inviscid liquid (heavy) with an exterior fluid of zero density ($A_t = 1$) and no surface tension. The numerics use a boundary integral method (BIM later on). Due to strong numerical instabilities, a careful treatment of the interface using conformal mapping is needed as explained below. The results are then shown and compared with the theory.

**ASYMPTOTIC ANALYSIS AND NUMERICAL METHOD**

We consider the two-dimensional motion of an inviscid fluid above a vacuum, subject to a negative acceleration $-g$. A periodic sine perturbation of the interface of wave number $k$ is implemented as initial conditions. Neglecting surface tension, the equations of motion have no control parameter after rescaling the time, the position and the velocity potential $\phi$ by factors $\sqrt{gk}$, $k$ and $\sqrt{k^3/g}$ respectively. The interface is described by $y = \alpha(x,t)$, where $y$ is the direction along the gravity and $x$ orthogonal to it (see figure [2]). The velocity field $U = (u,v)$ satisfies the dimensionless Euler equation

$$\frac{dU}{dt} = -\nabla P + e_y$$

where $P(x,y,t)$ is the pressure, $e_y$ the non-dimensional acceleration due to gravity and the fluid density $\rho = 1$. The kinetic equation for the interface reads:

$$\frac{\partial \alpha(x,t)}{\partial t} + u \frac{\partial \alpha(x,t)}{\partial x} = v$$

with the velocity field $(u,v)$ evaluated at the interface $(x, \alpha(x,t))$. Starting at time $t = 0$ with a small sine amplitude interface, we observe for large time that the fluid particles located in the vicinity of the tiny spikes come from an almost free fall from the initial interface region. Therefore, following [13], we assume quasi-parallel steady flow for the velocity field which gives then in the tip region $|u| \ll |v|$ and:

$$v \sim \sqrt{2y}$$

with $y \sim \frac{1}{2}t^2$ for large time. Writing a perturbation expansion of the velocity field in the tip region $|x| \ll y$, we in fact consider:

$$v = \sqrt{2(y + f(x,y,t))}$$

with $f(x,y,t) \ll y$. Taking a Taylor expansion in $x$ of the perturbation $f$, we obtain by symmetry:

$$v = \sqrt{2y + \frac{f_0(y,t)}{2y}} + x^2 \frac{f_2(y,t)}{2\sqrt{2y}} + O(x^4)$$

We limit our expansion to the second order in $x$ for the velocity field later on. Incompressibility gives:

$$u = -\left( \sqrt{\frac{1}{2y} + \frac{\partial f_0(y,t)/\sqrt{2y}}{\partial y}} \right) x + O(x^3).$$

At the leading order (where we neglect even the perturbation $f(x,y,t)$) we obtain the following expression for the interface location:

$$\frac{\partial \alpha(x,t)}{\partial t} - \frac{x}{\sqrt{2\alpha(x,t)}} \frac{\partial \alpha(x,t)}{\partial x} = 2 \alpha(x,t)$$

which can be solved using the methods of characteristics (see [13]). Writing $\alpha(x,t) = t(\frac{1}{2} - \gamma(x,t))$ and noting that $\gamma(x,t) \ll t/2$ in the spike region, we obtain, after linearisation:

$$\frac{\partial \gamma(x,t)}{\partial t} - \frac{x}{t} \frac{\partial \gamma(x,t)}{\partial x} = 0$$

which has self-similar solution of the form $\gamma(x,t) = \theta(xt)$. A first conclusion can be drawn about the curvature of its local tangent:

$$\kappa = t^3 \theta''(0)$$

(1)

The next order terms of the expansion allow the determination of the function $f_0(y,t)$ near the tip. Using the constant value of the pressure at the interface we use the projection of the Euler equation at the interface on its local tangent:

$$\frac{du}{dt} + \frac{\partial \alpha(x,t)}{\partial x} \frac{dv}{dt} = \frac{\partial \alpha(x,t)}{\partial x}.$$

Since on the interface $dP(x,\alpha(x,t),t)/dx = 0$. We develop this equation at first non-zero order (which will end up to be the first order in $x$) with the expansion $\theta(xt) = \theta(0) + x^2 \theta''(0)/2 + O(x^4)$. Remembering that $|f| \ll y$, we can neglect also the large scale terms $\partial^2 f_0(y,t)/\sqrt{2y}$ and $\sqrt{2y} \phi^2 f_0(y,t)/\sqrt{2y}$ with respect to the others. We obtain finally for the tip position $y = y_s$:

$$\frac{\partial f_0(y_s,t)}{\partial t} + \sqrt{2y_s} \frac{\partial f_0(y_s,t)}{\partial y} = \frac{df_0(y_s,t)}{dt} = \frac{1}{\sqrt{2y_s}}$$

(2)

Recalling that: $\frac{dy}{dt} = \sqrt{2y_s} + \frac{f_0(y_s,t)}{\sqrt{2y_s}}$, we obtain for the tip acceleration at leading order:

$$\frac{d^2 y_s}{dt^2} = 1 + \frac{1}{\sqrt{2y_s}} \frac{df_0(y_s,t)}{dt} = 1 + \frac{2}{t^3 \theta''(0)}$$
We know that the non-dimensional Bernoulli equation on the free surface is solved using a pressure stream function, and that the conformal map transforms the periodic domain $\Omega$ into a closed domain $M$. The position of the spike is shown on figure 3 as function of time. We observe that the asymptotics dynamics are very well approximated by the relation $y_s = \frac{1}{2}g(t - t_0)^2$ as shown in the inset to the figure with $t_0 = 3.74$. This remarkable behavior, in good agreement with the free fall hypothesis, suggests that $t_0$ is the time delay accounting for the initial exponential development of the instability. We will therefore present further data on the curvature dependance and the acceleration of the tip as functions of this delayed time $t - t_0$ instead of $t$. The curvature $\kappa_s$ at the tip is then shown on figure 4.

RESULTS AND DISCUSSIONS

We have performed numerical simulations of the Rayleigh-Taylor instability using the numerical method described above. We start with a small amplitude sine-mode. The unavoidable numerical noise cannot be damped by the numerics and the calculations always end up subject to numerical instabilities. Nevertheless, we emphasize that the numerical scheme used here is remarkably robust and can be accurately evolved to reach the large time where the asymptotics discussed above are valid. Comparing our simulations with recent numerical works [5, 6], we have been able to run the dynamics at least twice as far which corresponds roughly to an increase of a factor of 8 in the tip’s curvature.

FIG. 2: Conformal map used to transform the physical periodic plane $\Omega$ into a closed domain $M$.

FIG. 3: Position of the spike $y_s(t)$ as a function of time. The inset shows in a log-log plot the spike position (black curve) as function of time $t - t_0$ with $t_0 = 3.74$ obtained by a second order polynomial fit of $y_s$. The dashed line shows the expected behavior $\frac{1}{2}t^2$. 

\[
\frac{\partial \varphi}{\partial t} = -\frac{1}{2}(\nabla \varphi)^2 + y, \quad (3)
\]

where the velocity potential $\varphi$ is a harmonic function in the fluid domain $\Omega$ :

\[
\Delta \varphi = 0 \quad (4)
\]

The kinematic condition on the free surface expresses the fact that fluid particles move with the same normal velocity than the free surface itself :

\[
\frac{dx}{dt} \cdot n = \nabla \varphi \cdot n \quad (5)
\]

Knowing $\varphi$ on the free surface at a given time-step, we search for the solution of equation 4 that satisfies this boundary condition 5. We use the complex potential $\beta(z) = \varphi + i\psi$ and the conformal map $f(z) = \exp(-iz)$ (Cf. Figure 2), where $z = x + iy$ and $\psi$ is the stream function. The conformal map transforms the periodic domain $\Omega$ into the closed domain $M$. Since $\psi$ is harmonic inside $\Omega$, $\beta(z)$ is analytic inside $\Omega$ and therefore $\gamma(\zeta) = \beta(f(z))$ is analytic inside $M$. Using Cauchy’s theorem, we obtain a Fredholm equation of the second kind for the stream function $\psi$ which is solved using discretization of the free surface ($\partial \Omega$ and thus $\partial M$). This linear system of equations is solved using a $LU$ decomposition. Once we know $\psi$ on each point on $\partial M$, the complex velocity of each marker in the physical plane is given by :

\[
\frac{d\beta}{dz} = u - iv \quad (6)
\]

where $u$ and $v$ are the horizontal and vertical velocities respectively. This complex velocity is computed with a finite difference scheme using the values of the complex potential on the collocation points on $\partial \Omega$. The position of the markers (kinematic condition) and the value of the velocity potential on each of these markers (Bernoulli equation) are then updated in time using a fourth order Runge-Kutta method.
The large time asymptotic behavior is similarly found to follow the cubic law (see equation 1) with $\theta''(0) = 1.5$. In addition, the acceleration of the tip is computed by finite differences on the tip velocity and the overshoot in the acceleration is presented on figure 5. We observe that the results look noisier than the two previous ones. Two factors can explain such noise: firstly, we are looking to a finite difference which decreases to zero so that the numerical errors are relatively more important. However, we note that the overshoot in acceleration shows a good agreement with the $1/t^5$ law, noting that no adjustable parameter is used in this comparison. Moreover, the self-similar structure of the interface near the tip has been exhibited on figure 6. We observe after the proper rescaling on the left part of the figure that the interface profiles collapse onto a single curve near the spike.

We have thus exhibited large times numerical simulations of the Rayleigh-Taylor instability which present asymptotic scaling behavior in agreement with theoretical predictions using Taylor expansions of the free fall velocity field at the spike[15]. Although our numerics always stops due to numerical instability, we have been able to reach large time enough to exhibit the cubic power in time dependance for the spike curvature and the inverse of the quintic power of time decreasing of the overshoot in acceleration.

It is our pleasure to thank J. Ashmore for useful comments. We acknowledge also the support of CEA through the contract CEA/DIF N 4600051147/P6H29.
