Intracoronary near-infrared spectroscopy and the risk of future cardiovascular events

Sofia Karlsson,1 Erik Anesäter,2 Klara Fransson,1 Pontus Andell,1 Jonas Persson,2 David Erlinge1

ABSTRACT

Objectives The objectives of this study were to investigate if findings by intracoronary near-infrared spectroscopy (NIRS) and intravascular ultrasound (IVUS) are associated with future cardiovascular events and if NIRS can differentiate culprit from non-culprit segments in patients with coronary artery disease.

Methods The study included 144 patients with coronary artery disease undergoing percutaneous coronary intervention and combined NIRS-IVUS imaging at two Swedish hospitals. The NIRS-derived lipid core burden index (LCBI), the 4 mm segment with maximum LCBI (MaxLCBI4mm) and the IVUS-derived maximum plaque burden (MaxPB) were analyzed within the culprit segment and continuous 10 mm non-culprit segments of the index culprit vessels. The association with future major adverse cardiac events and continuous 10 med. (MaxPB) were analyzed within the culprit segment and continuous 10 mm non-culprit segments of the index culprit vessels. The association with future major adverse cardiac events and continuous 10

Results A non-culprit maxLCBI4mm ≥400 (HR: 3.67, 95% CI 1.46 to 9.23, p=0.006) and a non-culprit LCBI ≥ median (HR: 3.08, 95% CI 1.11 to 8.56, p=0.031) were both significantly associated with MACCE, whereas a non-culprit MaxPB ≥70% (HR: 0.61, 95% CI 0.08 to 4.59, p=0.63) was not. The culprit segments had larger lipid cores compared with non-culprit segments (MaxLCBI4mm 425 vs 74, p<0.001), and the ROC analysis showed that NIRS can differentiate culprit against non-culprit segments (c-statistics: 0.85, 95% CI 0.81 to 0.89).

Conclusion A maxLCBI4mm ≥400 and LCBI ≥ median, assessed by NIRS in non-culprit segments of a culprit artery, were significantly associated with patient-level MACCE. NIRS furthermore adequately discriminated culprit against non-culprit segments in patients with coronary artery disease.

INTRODUCTION

Ischaemic heart disease is one of the leading causes of death worldwide, and patients with a history of myocardial infarction remain at an increased risk of future cardiovascular events, despite secondary preventive medications that are known to improve outcome.1 Hence, further research to improve the foreseeing of cardiovascular events is needed.

As angiography has limited possibilities to detect vulnerable plaques, new intravascular imaging techniques have evolved. Intravascular ultrasound (IVUS) is a catheter-based imaging modality exploring the coronary vessel wall from the inside, and the ability of IVUS to identify high-risk plaques has previously been demonstrated in prospective studies.2–4 Intracoronary near-infrared spectroscopy (NIRS) is a novel intravascular imaging modality, developed and validated to detect atherosclerotic lipid-rich lesions within the coronary arteries in living humans.5–7 The NIRS analysis generates a lipid core burden...
index (LCBI) based on the amount of lipid in the investigated artery, and the 4 mm segment with maximum LCBI is known as the MaxLCBI$_{4mm}$. Observational studies have reported NIRS-detected lipid-rich plaques at the majority of culprit sites in patients with acute coronary syndrome (ACS), and a MaxLCBI$_{4mm}$ ≥ 400 has been suggested to be a specific signature of plaques that underlie myocardial infarction. The ability of combined NIRS-IVUS to prospectively detect vulnerable plaques and foresee clinical events however still warrants further investigation, and the aim of this study was to investigate if combined NIRS-IVUS findings in non-culprit segments of a culprit vessel are associated with future cardiovascular events and if NIRS accurately can differentiate culprit from non-culprit segments in patients with coronary artery disease.

METHODS

Study population

Consecutive patients undergoing percutaneous coronary intervention and combined NIRS-IVUS imaging during an index coronary catheterisation at Skåne University Hospital, Lund, Sweden, and Danderyd Hospital, Stockholm, Sweden, between 2012 and 2015 were screened for inclusion in this study. Patients meeting the following inclusion criteria: age above 18 years, coronary catheterisation due to suspected ischaemic coronary disease and combined NIRS-IVUS imaging of the culprit segment and at least 10 mm of a non-culprit segment within a native coronary artery were retrospectively enrolled in this observational study. Patients referred to acute coronary artery bypass grafting (CABG) and patients without complete follow-up were excluded from further analysis.

NIRS-IVUS analyses

Combined NIRS-IVUS data were acquired using a 3.2 F coronary catheter (TVG Imaging System, Infraredx, Burlington, Massachusetts, USA), and the decision to perform combined NIRS-IVUS was made by the interventional cardiologist, and performed pre- and/or post-stent placement, in accordance with clinical IVUS guidelines. All NIRS-IVUS images included in the study were retrospectively analysed using either CAAS IntraVascular software (Pie Medical Imaging, Maastricht, The Netherlands) or the TVG imaging system consol (Infraredx, Burlington, Massachusetts, USA), blinded to patients’ characteristics and outcome. The culprit segment was identified in the combined NIRS-IVUS images by the corresponding angiography and defined as the region treated with balloon and/or stent placement during the index procedure. The remaining non-culprit regions of the investigated arteries were divided into 10 mm continuous non-culprit segments, excluding previously stented segments. All culprit and 10 mm non-culprit segments were analysed for LCBI, MaxLCBI$_{4mm}$ and the maximum plaque burden (MaxPB). The primary NIRS and IVUS findings were LCBI ≥ median, MaxLCBI$_{4mm}$ ≥ 400 and MaxPB ≥ 70%, based on knowledge from previous studies. The LCBI and MaxLCBI$_{4mm}$ were automatically provided by the NIRS-derived chemogram and the MaxPB was calculated by manual contouring of the external elastic membrane (EEM) and vessel lumen and defined as the area of plaque and media divided by EEM area. When combined NIRS-IVUS of the same coronary segments was performed both pre- and post-stent placement, the pre-stent imaging pullback was selected for the culprit analysis, and the post-stent imaging pullback was selected for the non-culprit follow-up analysis. Chemograms were considered uninterpretable and excluded if black areas, representing catheter artefacts and unreliable data, interfered the analyses. Baseline characteristics were registered at the time of the index catheterisation and enrolled in local NIRS-IVUS registries.

Primary endpoint

The primary endpoint of major adverse cardiovascular and cerebrovascular event (MACCE) was defined as all-cause mortality, recurrent ACS requiring revascularisation and cerebrovascular events (transitory ischaemic attack or stroke) as in previous NIRS-IVUS studies. Recurrent events related to the index culprit lesion or previously stented segments were not included in the analyses. Follow-up was recorded from medical records with a minimum follow-up time of 1 year.

Statistics

Normally distributed continuous variables were presented as mean±SD, and non-normally distributed continuous variables were presented as median and IQR. Categorical variables were displayed using numbers and percentages. Differences between groups of patients with non-culprit LCBI ≥ median versus LCBI < median, MaxLCBI$_{4mm}$ ≥ 400 versus MaxLCBI$_{4mm}$ < 400 and a non-culprit MaxPB ≥ 70% versus MaxPB < 70% were assessed with the χ² test for categorical variables and the Student’s t-test or Mann-Whitney U test for continuous variables, as appropriate.

Univariable and multivariable analyses of the primary endpoint were done with Cox regression models, and Kaplan-Meier curves of MACCE were plotted and analysed with the log-rank test. The multivariable Cox regressions models were adjusted for age and gender, as decided a priori. The number of covariates included in the multivariable model was limited in order not to overfit the models. The proportionality assumption of Cox regression was tested. P values < 0.05 were considered significant.

Sensitivity analyses

Additional Cox regression analyses were performed: (1) with an endpoint including only cardiovascular deaths instead of all-cause mortality and (2) with an endpoint representing catheter artefacts and unreliable data, interfered the analyses. Baseline characteristics were registered at the time of the index catheterisation and enrolled in local NIRS-IVUS registries.
not encountering cerebrovascular events. Furthermore, different thresholds of MaxLCBI\textsubscript{4mm} and MaxPB were evaluated.

**NIRS findings in culprit versus non-culprit segments**

A receiver operating characteristics (ROC) curve was constructed to evaluate the capacity of the NIRS-derived MaxLCBI\textsubscript{4mm} to discriminate the culprit segment against a background of non-culprit segments. Additionally, ROC curves including the subgroups of patients with (1) MI and (2) STEMI were constructed and the sensitivity and specificity of the previously described threshold of MaxLCBI\textsubscript{4mm} $\geq 400$, previously confirmed to discriminate culprit against non-culprit segments in patients with ACS,\textsuperscript{9} was evaluated. Culprit lesions where combined NIRS-IVUS revealed stent thrombosis were not included in the culprit analysis due to its different mechanism of thrombosis.

The statistical calculations were performed in SPSS Statistics V.24.0 and STATA V.14.2.

**RESULTS**

**Study population**

Between July 2012 and January 2015, a total of 168 patients were enrolled in this study. Eight patients were excluded due to incomplete follow-up, two patients were referred to CABG and an additional 14 patients were excluded due to uninterpretable NIRS images (figure 1). The remaining 144 patients constitute the study population and consisted of 102 (70.8%) men, and the mean age was 66.5 years. The index procedure included 43.8% ST-elevation myocardial infarction (STEMI) (n=63), 24.3% non-STEMI (n=35), 13.9% unstable angina (n=20) and 18.1% stable angina (n=26). Investigated arteries were left anterior descending coronary artery in 66.0% (n=95), left circumflex coronary artery 12.5% (n=18) and right coronary artery 21.5% (n=31) and the median length of the investigated arteries was 60.0±21.1 mm.

**Baseline characteristics in relation to NIRS and IVUS findings**

Baseline characteristics in relation to NIRS and IVUS findings are presented in table 1. The median non-culprit LCBI (based on the mean of all 10 mm non-culprit segments within each investigated artery) was 65, and patients with non-culprit LCBI $<65$ were similar to the patients with non-culprit LCBI $\geq 65$ regarding all baseline characteristics except hypertension, which was more common in the group with non-culprit LCBI $<65$ versus LCBI $\geq 65$, 62.5% versus 44.4%, respectively. In total, 36 patients had a non-culprit lesion with MaxLCBI\textsubscript{4mm} $\geq 400$, and the only significant difference in baseline characteristics between patients with and without a non-culprit MaxLCBI\textsubscript{4mm} $\geq 400$ was high-density lipoprotein (HDL) levels, which were lower in the group with a non-culprit MaxLCBI\textsubscript{4mm} $\geq 400$ (p value 0.04). Furthermore, 13 patients had a non-culprit segment with a MaxPB $\geq 70\%$, and there were no significant baseline differences between the group with and without a non-culprit MaxPB $\geq 70\%$. In total, eight patients had a non-culprit lesions with both MaxLCBI\textsubscript{4mm} $\geq 400$ and MaxPB $\geq 70\%$.

**NIRS-IVUS findings in relation to patient-level MACCE**

During a mean follow-up time of 1076±483 days, MACCE occurred in 19 (13.2%) patients, and these were comprised of all-cause mortality: 10 events (52.6%), ACS requiring revascularisation: 7 events (36.8%) and cerebrovascular events: 2 events (10.5%). Of the 10 cases of all-cause mortality, one event was caused by cancer and the remaining nine were cardiovascular deaths.\textsuperscript{18} The mean time to MACCE was 412±402 days. Using univariate Cox regressions, a non-culprit MaxLCBI\textsubscript{4mm} $\geq 400$ was significantly associated with future MACCE (univariable HR 2.91, 95% CI 1.18–7.17, p=0.020) and the Kaplan Meier failure estimates, stratified by MaxLCBI\textsubscript{4mm} $\geq 400$,

ACEi, angetensin converting enzyme inhibitor; ARB, angiotensin II receptor blocker; Ca blocker, calcium channel blocker; HDL, high-density lipoprotein; LCBI, lipid core burden index; LDL, low-density lipoprotein; MI, myocardial infarction; MaxLCBI_{4mm}, 4 mm segment with maximum lipid core burden index; MaxPB, maximum plaque burden; NSTEMI, non-ST-elevation myocardial infarction; SAP, stable angina pectoris; STEMI, ST-elevation myocardial infarction; TIA, transitory ischaemic attack; UAP, unstable angina pectoris.

Figure 2  (A) Kaplan-Meier estimates of MACCE in patients with a non-culprit MaxLCBI_{4mm} ≥400 and MaxLCBI_{4mm} <400. (B) Kaplan-Meier estimates of MACCE in patients with a non-culprit LCBI ≥65 and LCBI <65. LCBI, lipid core burden index; MACCE, major adverse cardiovascular and cerebrovascular events; MaxLCBI_{4mm}, 4 mm segment with maximum lipid core burden index.
are presented in figure 2A. The adjusted multivariable Cox regression showed a similarly significant association with MACCE (multivariable HR 3.67, 95% CI 1.46 to 9.23, p=0.006). A non-culprit LCBI ≥65 was also significantly associated with MACCE (univariable HR 2.93, 95% CI 1.05 to 8.13, p=0.039) and the Kaplan Meier curve is presented in figure 2B. This association remained consistent after adjustments in the multivariable Cox regression (multivariable HR 3.08, 95% CI 1.11 to 8.56, p=0.031). There was no significant association between a non-culprit MaxPB ≥70% and MACCE (univariable HR 0.62, 95% CI 0.08 to 4.65, p=0.64, multivariable HR 0.61 95% CI 0.08 to 4.59, p=0.63), nor was there any significant association between the eight patients with non-culprit lesions containing both MaxLCBI in mm ≥400 and MaxPB ≥70% and MACCE during follow-up (univariable HR 0.046, 95% CI 0.0 to 250.3, p=0.48).

NIRS-IVUS findings and the relation to lesion-level MACCE
As the majority of ACS that required revascularisation during follow-up in this study originated from non-culprit segments not imaged by combined NIRS-IVUS during the index procedure, lesion-level statistical analyses were not feasible to perform. However, in two cases, the forthcoming culprit lesions were investigated at baseline. In the first case, combined NIRS-IVUS detected a lipid-rich lesion (MaxLCBI in mm=573, MaxPB 60%) at the time of the index procedure with no angiographic evidence of stenosis at baseline. An ACS requiring revascularisation developed 107 days from the index procedure, at the specific site of the baseline lipid-rich lesion. In the other case, 258 days from the index procedure, a recurrent ACS requiring revascularisation developed in a segment where combined NIRS-IVUS demonstrated calcification but no lipid at baseline (MaxLCBI in mm=0, MaxPB 45%).

Sensitivity analyses
The Cox regression analyses of MACCE and different thresholds of MaxLCBI in mm and MaxPB are presented in table 2. In summary, the presence of a MaxLCBI in mm ≥200, MaxLCBI in mm ≥400 and MaxLCBI in mm ≥500 were all significantly associated with an increased risk of MACCE, whereas none of the investigated thresholds of MaxPB showed any significant relationship with MACCE. The sensitivity analyses: (1) encountering only cardiovascular deaths and (2) excluding cerebrovascular event furthermore demonstrated results consistent with the primary endpoint analysis (online supplementary table 1).

NIRS findings in culprit versus non-culprit segments
The median MaxLCBI in mm in culprit lesions was significantly higher compared with the median maxLCBI in mm in non-culprit segments (425 vs 74, p<0.001), and the ROC curve analysis found MaxLCBI in mm to accurately discriminate culprit from non-culprit segments (c-statistics: 0.85, 95% CI 0.81 to 0.89) (figure 3a–c). The threshold of MaxLCBI in mm ≥400 accurately classified 85% of the segments with a specificity of 92.9% and sensitivity of 54.5%. Among the subgroup of patients with STEMI, c-statistics was 0.92, 95% CI 0.87 to 0.96, and the threshold of MaxLCBI in mm ≥400 identified the STEMI culprit lesions with a specificity and sensitivity of 91.7% and 71.4%, respectively.

| MaxLCBI in mm ≥400 | Macce n (%) | Multivariable HR 95% CI | P value |
|---------------------|-------------|--------------------------|---------|
| 72 (19.4) | 3.08 (1.11 to 8.56) | 0.031 |
| 67 (20.9) | 4.32 (1.55 to 12.1) | 0.005 |
| 36 (25.0) | 3.67 (1.46 to 9.23) | 0.006 |
| 18 (27.8) | 2.98 (1.06 to 8.37) | 0.038 |
| 9 (22.2) | 1.87 (0.42 to 8.38) | 0.41 |
| 23 (13.0) | 0.91 (0.26 to 3.17) | 0.86 |

IVUS, intravascular ultrasound; LCBI, lipid core burden index; MACCE, major adverse cardiovascular and cerebrovascular events; MaxLCBI in mm, 4mm segment with maximum lipid core burden index; MaxPB, maximum plaque burden; NIRS, near-infrared spectroscopy.

DISCUSSION
The primary results of this study were that a MaxLCBI in mm ≥400 and LCBI≥65, assessed by NIRS in non-culprit segments of a culprit artery, were significantly associated with patient-level MACCE, whereas the IVUS-derived MaxPB was not. Additionally, this study confirms that NIRS adequately discriminate culprit from non-culprit segments in patients with coronary disease, with the highest specificity and sensitivity among patients with STEMI.

As previously discussed, NIRS detects lipids at most culprit sites in patients with ACS and given the assumption that the NIRS-detected signs of lipids are present also prior to the event, NIRS may be able to prospectively detect vulnerable plaques. In this study, intracoronary imaging was performed in the culprit vessel alone and the majority of recurrent ACS occurred in segments not imaged by combined NIRS-IVUS at baseline. Whether a large lipid-rich plaque was present at the time of the index procedure or not is therefore unknown. Nevertheless, the presence of a NIRS-detected MaxLCBI in mm ≥400 within a non-culprit segment of the culprit artery, as well as a non-culprit LCBI ≥ median, was both significantly associated with MACCE, representing a patient-level risk of adverse cardiovascular events identified by NIRS. Previously, reports from the ATHEROREMO-NIRS (Part of the European Collaborative Project on Inflammation and Vascular Wall Remodeling in Atherosclerosis – Intravascular Ultrasound Study [AtheroRemoIVUS])11 14 and ORACLE-NIRS (the lipid cORe plaque association

with CLinical events)\textsuperscript{13} registries have demonstrated an association between NIRS findings in non-culprit vessels and future patient-level cardiovascular events. Moreover, Madder \textit{et al.}\textsuperscript{12} reported the association between NIRS-detected lipid-rich lesions in non-stented sites of a target coronary artery and patient-level MACCE, similarly to this study. Ur concurrent results with these prior studies, now demonstrated in a two-centre design, support and substantiate the proposed ability of NIRS to identify vulnerable patients.

The primary NIRS and IVUS findings analysed in this study were a non-culprit LCBI $\geq$ median, MaxLCBI_{4mm} $\geq$400 and MaxPB $\geq$70%. The sensitivity analyses however included additional thresholds of both MaxLCBI_{4mm} and MaxPB. There was a numerical increase in the rate of events with higher thresholds of MaxLCBI_{4mm} except for MaxLCBI_{4mm} $\geq$2600, which was present only in two patients. The HRs however did not increase with higher thresholds of MaxLCBI_{4mm}. Our findings suggest that the presence of a NIRS-detected lipid-rich lesion is a risk marker associated with a higher risk of adverse outcome. What threshold that best predicts future cardiovascular events however still warrants further investigation. In our study, as well as in the previous study by Madder \textit{et al.}\textsuperscript{12} the IVUS-derived non-culprit MaxPB was not associated with adverse outcome, and there are a few possible explanations as to why no such association was found. First, this study included IVUS imaging of the culprit vessel alone, in contrast to previous IVUS-studies that performed three-vessel IVUS imaging,\textsuperscript{2–4} and the number of patients with MaxPB $\geq$70% was consequently low. Moreover, the non-blinded use of IVUS-guidance during the index procedure and the beforehand known risk associated with a non-culprit plaque burden $\geq$70% could also have contributed to the low number of patients and events, which furthermore made statistical analyses uncertain.

Baseline characteristics were similar between the compared groups in this study. However, an interesting difference in HDL levels was noted between individuals with and without a non-culprit MaxLCBI_{4mm} $\geq$400, with lower HDL levels among patients with a MaxLCBI_{4mm} $\geq$400. This finding is in concordance with the proposed antiatherogenic properties held by HDL.\textsuperscript{19, 20} However, no corresponding difference was detected in levels of low-density lipoprotein (LDL) cholesterol.\textsuperscript{21} In alignment with these findings, a recent study by Honda \textit{et al.}\textsuperscript{22} concluded that change in HDL-levels are inversely associated with the change in coronary plaque lipid burden.
as assessed by NIRS, whereas no association to LDL levels was found. The association between NIRS findings and HDL levels and its potential clinical importance need further investigation in future studies.

Despite the promising results of NIRS, several lesions with MaxLCBI_{\text{mm}} \geq 400 did not cause a future cardiovascular event during the follow-up time in this study, and secondary preventive medication is still the gold standard in treating non-culprit lesions without flow-limiting stenosis. However, one of the large lipid accumulations with MaxLCBI_{\text{mm}} \geq 400 detected at the index procedure did cause an ACS during follow-up. This observation sustains the hypothesis that NIRS may be valuable in the search for the vulnerable plaques, even though the limited sample size with imaging of the culprit vessel alone in this study only allow for hypotheses. If combined NIRS-IVUS imaging can predict both patients and plaques at higher risk of future cardiovascular events is currently tested in the large ongoing Lipid-Rich Plaque study (ClinicalTrials.gov NCT02033094) and the PROSPECT II trial (ClinicalTrials.gov NCT02171065) and if local treatment of non-flow limiting high risk plaques is effective will be evaluated in the randomised PROSPECT ABSORB substudy. Complete intravascular imaging of all three coronary arteries and the combination of additional intravascular imaging modalities could possibly also help discriminate the vulnerable plaques.

**Limitations**

This study holds limitations in need of consideration. First, this was an observational study of retrospectively enrolled patients, and the decision to perform combined NIRS-IVUS was made by the treating physician. Although consecutive patients were included and prospectively followed, the study population may represent a selected population suitable for intravascular imaging. Second, although the NIRS-IVUS analysis was performed in a routine manner, blinded to the outcome and with standardised definitions, a user-dependent variation may have affected the results. Finally, even though this study included patients from two centres and represents the largest study yet to demonstrate the association between NIRS findings in non-culprit segments of the culprit artery and adverse outcome, the sample size was limited, and future larger studies are warranted to confirm our results and to investigate the ability of combined NIRS-IVUS imaging to identify high-risk patients and vulnerable plaques.

**CONCLUSION**

In conclusion, this study demonstrates that a MaxLCBI_{\text{mm}} \geq 400 and LCBI \geq 2 median, assessed by NIRS in non-culprit segments of a culprit artery, are significantly and independently associated with patient-level MACCE. NIRS also held the capacity to accurately differentiate culprit from non-culprit segments among patients with coronary artery disease. These results support previous knowledge regarding the ability of NIRS to identify patients at risk for future cardiovascular events, but larger prospective trials are needed to confirm our findings and to evaluate the ability of combined NIRS-IVUS to prospectively detect vulnerable plaques at risk of future events.

**Acknowledgements**

The authors would like to thank the staff members at the participating coronary care units for their help throughout this study.

**Contributors**

DE contributed with the study design, patient enrolment, data collection, revised the draft paper and is the overall responsible author for this study. SK contributed with the study design, cleaned and analysed the data including imaging and statistical analyses and drafted and revised the manuscript. EA contributed with the study design, cleaned and analysed the data including imaging analyses and revised the draft paper. KE analysed the data including imaging and statistical analyses and drafted and revised the manuscript. PA contributed to the study design and statistical plan and revised the draft paper. JP contributed with study design, patient enrolment, data collection and revised the draft paper.
