ABSTRACT

We investigate the mid-infrared properties of the largest (42 objects) sample of radio-loud narrow-line Seyfert 1 (RL NLS1) collected to date, using data from the Wide-field Infrared Survey Explorer (WISE). We analyse the mid-IR colours of these objects and compare them to what is expected from different combinations of AGN and galaxy templates. We find that, in general, the host galaxy emission gives an important contribution to the observed mid-IR flux in particular at the longest wavelengths (W3, at 12 µm, and W4, at 22 µm). In about half of the sources (22 objects) we observe a very red mid-IR colour (W4-W3>2.5) that can be explained only using a starburst galaxy template (M82). Using the 22 µm luminosities, corrected for the AGN contribution, we have then estimated the star-formation rate for 20 of these “red” RL NLS1, finding values ranging from 10 to 500 M⊙ yr⁻¹. For the RL NLS1 showing bluer colours, instead, we cannot exclude the presence of a star-forming host galaxy although, on average, we expect a lower star-formation rate. Studying the radio (1.4 GHz) to mid-IR (22 µm) flux ratios of the RL NLS1 in the sample we found that in ~10 objects the star-forming activity could represent the most important component also at radio frequencies, in addition (or in alternative) to the relativistic jet. We conclude that both the mid-IR and the radio emission of RL NLS1 are a mixture of different components, including the relativistic jet, the dusty torus and an intense star-forming activity.

Key words: galaxies: active - galaxies: nuclei - galaxies: jets - galaxies: starburst

1 INTRODUCTION

The importance of the nuclear active accretion phase (AGN) in the context of galaxy evolution has been fully recognized only in the last years (e.g. see Heckman & Best 2014 for a recent review). According to the galaxy-AGN co-evolution scenario, at high redshifts, both star-forming (SF) activity and nuclear accretion must have proceeded simultaneously and at high rates thanks to the abundance of cold gas and to the frequent galaxy mergers that made the gas available for both processes. In a second phase, when the AGN luminosity was high enough to expel the gas from the galaxy, both star-formation and accretion rates gradually reduced eventually leading to a “passive” elliptical hosting a quiescent supermassive black-hole.

At low redshift, however, galaxy interactions and/or internal galaxy dynamics can destabilize the residual gas and make it available for new episodes of SF and nuclear activity at high accretion rates. Mathur (2006) has proposed that the so-called Narrow-Line Seyfert 1 galaxies (NLS1), a peculiar sub-class of AGN that is characterized by rapidly accreting central black-holes with relatively small masses (between 10⁷ and 10⁸ M⊙), may represent the low-redshift, low-luminosity analogues of the first high-z quasars, hosted by rejuvenated, gas-rich galaxies. In support to this hypothesis, it has been noted that NLS1 are more frequently associated to host galaxies with large levels of star-forming activity than Broad Line Seyfert 1 (BLS1) galaxies (e.g. Deo, Crenshaw & Kraemer 2006; Sani et al. 2010, 2012). In this context, NLS1 could be systems that are building up mass, evolving eventually into BLS1. The time-scale of this process should depend on the radiative efficiency of the accretion process, as discussed in Orban de Xivry et al. (2013).

Interestingly, NLS1 may be considered as “young systems” also from the radio point-of-view. NLS1s are typically radio-quiet (RQ) sources with only a small fraction that can be classified as radio-loud (RL, ~7%, Komossa et al. 2006) and about 50 in total known to date, Foschini (2011). The radio properties of

© 0000 RAS
these RL NLS1 seem to be different from those observed in RL BLS1 mainly because of the lack of extended radio structures, except for very few cases (e.g. [Doi et al. 2012]). It has been proposed that at least some of the RL NLS1 can be associated to young radiogalaxies whose relativistic jet is still digging its way through the ISM of the host galaxy possibly evolving into a “classical” giant radiogalaxy [Moran 2004; Oshlack, Webster & Whiting 2001; Gallo et al. 2006; Komossa et al. 2006; Yuan et al. 2008; Caccianiga et al. 2014]. Notably, young and compact radiogalaxies are observed also in the 3 radio-loud QSO discovered to date at z–6 ([Frey et al. 2011, 2012]). This further increases the possible analogies between local NLS1 and high-z QSO.

The possibility that NLS1 are “young” systems where the AGN-galaxy co-evolution is taking place and where, in some cases, a young relativistic jet is ejected and observed in the early phase of its evolution, is intriguing: the study of these sources may offer a unique opportunity of investigating the co-evolution mechanism in both radio-loud and radio-quiet objects at relatively low-redshifts where the observational constraints are less challenging with respect to high-z QSO.

In this paper we focus on the radio-loud fraction of NLS1 that is still poorly studied. In particular, we want to assess if RL NLS1 are similar to RQ NLS1 for what concerns their preference in being hosted by star-forming galaxies. To date, only few RL NLS1 have been studied from this point of view. Optical imaging has revealed the existence of arms or circumnuclear rings (possibly the consequence of a recent merger) and the presence of a circumnuclear starburst in at least one RL NLS1 (1H 0323+342, Zhou et al. 2007; [Antón, Browne & Marcha 2008; León-Tavares et al. 2014]). In a recent paper (Caccianiga et al. 2014), a new case of RL NLS1 has been presented whose Spectral Energy Distribution (SED) is strongly suggestive of the presence of a quite intense star-formation (~50 M⊙ yr⁻¹). The presence of this intense SF was revealed by the mid-infrared (mid-IR) data at 12 and 22µm from the Wide-field Infrared Survey Explorer (WISE) catalogue (Wright et al. 2010) that showed a clear excess with respect to a typical dust emission from a radio-quiet AGN or to the IR non-thermal spectrum coming from a jet. We now want to extend such a result on a large sample of RL NLS1 to establish whether the presence of star-formation is a peculiar characteristic of some isolated sources or, instead, is a global property of the entire class.

The sample and the data used in this study are presented in Section 2. In Section 3 we discuss how the mid-IR colours (particularly those including the 22µm band) of the sources cannot be satisfactorily explained by the AGN emission alone. In Section 4 we consider the effect of galaxy emission on the observed IR colours and we infer the presence of a star-forming host in many objects of the sample. In Section 5 we compare the 1.4 GHz to 22µm flux ratios of the RL NLS1 with those of blazars and infrared galaxies while in Section 6 we estimate the star-formation rate (SFR) present in the sources with the reddest W3-W4 colours. Conclusions are finally presented in Section 7.

Throughout the paper we assume a flat ΛCDM cosmology with H₀=71 km s⁻¹ Mpc⁻¹, Ω_m=0.7 and Ω_Λ=0.3. Spectral indices are defined assuming Sₜₜ or ν(power)

2 THE SAMPLE OF RL NLS1 AND WISE DATA

[Foschini et al. 2015] has presented an extended study of the 42 RL NLS1 with a large radio-loudness parameter (>10, see [Foschini et al. 2015] for details) and a flat radio-spectrum (i.e. with blazar-like characteristics) discovered so far. Several pieces of information, from the radio to the X-ray and gamma-ray band, have been collected and studied. The physical properties of the inner supermassive black-hole (SMBH), like its mass and the accretion rate, have been also discussed. This is the largest sample of RL NLS1 collected so far and, therefore, it represents the best starting point to study the incidence of star-formation in the galaxies hosting these AGNs. It should be noted, however, that the type of selection of this sample, namely the requirement of a flat radio spectrum, strongly favours the presence of a relativistically beamed jet emission (as in blazars), which could be important also in the mid-IR band. This

Figure 1. The WISE colours of the RL NLS1 in the [Foschini et al. 2015] sample. Open and filled circles indicate the RL NLS1 with a redshift above and below 0.3 respectively. Sources circled by an open square are flagged as variable in the AllWISE catalogue while sources circled by triangles are flagged as extended. Different characteristic regions used to select AGNs are also plotted: the blazar “WISE Gamma-ray Strip” (WGS) for BL Lacs and FSRQ (BZB and BZQ respectively, solid lines, green and blue in the electronic version), as defined by [Massaro et al. 2013], the AGN wedge (dotted-dash line, magenta in the electronic version) as defined by [Mateos et al. 2013] and [Mateos et al. 2013] for X-ray selected AGNs, the mid-IR criterion (W1-W2>0.8, brown dotted line) proposed by [Stern et al. 2012]. Finally, the red dashed line indicates the region covered by a simple power-law spectrum (slopes of α=0, 1 and 2 are indicated by tidemarks).

1 The radio-loudness parameter used in [Foschini et al. 2015] is defined as the 5 GHz to 4400Å flux density ratio.
2 We note that only 22 sources out of 42 have a measured radio spectral index. Of these 22 objects, 20 have a flat slope (α_R<0.5) while 2 have α_R marginally above this value (0.55 and 0.58, respectively) but consistent with it taking into account the errors (see [Foschini et al. 2015] and also [Richards & Lister 2015] for the recently measured spectral index of J0953+2836). The remaining 20 sources have no information on the radio spectral index and should be considered more properly as “flat-spectrum candidates”.

© 0000 RAS, MNRAS 000, 000–000
Finally, 3 sources in the catalogue (J0324+0200, J0334−2800, J0426+3420) are flagged as extended in one or more bands in the AllWISE catalogue (ext, flg) where 9 sources lie outside it. 12 sources (78%) of the RL NLS1 occupy the region where blazars are usually found (blue and green solid regions) while 9 sources lie outside it. Most recently adopted to select different types of AGN (see figure caption for details). Not surprisingly, all the objects fulfill the AGN definition (W1−W2>0.8) proposed by Stern et al. (2012) and all but 2 lie in the AGN wedge discussed by Mateos et al. (2012, 2013). Most (78%) of the RL NLS1 occupy the region where blazars are usually found (blue and green solid regions) while 9 sources lie outside it. One source, in particular, shows a very blue W2−W3 colour (W2−W3=1.914), which is significantly different from the values observed in the other objects. This source, however, is one of the 3 objects flagged as possible variable (J0849+5108 and J0948+0022) intra-day variability has been studied by Jiang et al. (2012).

In Fig 1 we show the distribution of the WISE colours in the W1, W2 and W3 filters for the 41 RL NLS1 detected in all the 3 bands. In this figure we also show some characteristic regions recently adopted to select different types of AGN (see figure caption for details). Not surprisingly, all the objects fulfill the AGN definition (W1−W2>0.8) proposed by Stern et al. (2012) and all but 2 lie in the AGN wedge discussed by Mateos et al. (2012, 2013). Most (78%) of the RL NLS1 occupy the region where blazars are usually found (blue and green solid regions) while 9 sources lie outside it. One source, in particular, shows a very blue W2−W3 colour (W2−W3=1.914), which is significantly different from the values observed in the other objects. This source, however, is one of the 3 objects flagged as possible variable (J0849+5108 and J0948+0022) intra-day variability has been studied by Jiang et al. (2012).
Figure 2. The expected positions on the W1-W2 vs W2-W3 (left) and W1-W2 vs W3-W4 (right) plot of AGNs with different shapes of IR spectrum: 1) a simple power-law (black tick line) with slope ranging from 0.5 to 1.5; 2) a smooth broken power law, with slope before the break ranging from 0.5 to 1 and a slope of 1.5 after the break and with the break position varying within the WISE bands (dark blue shaded area); 3) a RQ AGN emission described by the 3 QSO templates from the SWIRE library (blue lines labelled as QSO, BQSO and TQSO, see text for a description and Polletta et al. 2007 for more details) and with a redshift ranging from 0 (indicated by a cross) to 0.9 (the maximum value of the sample); 4) a combination of RQ AGN emission plus a power-law spectrum (light blue shaded area). In particular, we show the result of all the different combinations of slopes (from 0.5 to 1.5), redshift (from 0 to 0.9) and relative RQ AGN to power-law normalization. The arrows in the upper-right corners show the expected effect of an extinction of $A_V=2$ mag at the mean redshift of the sample. An $A_V=2$ mag is the maximum value expected for type 1 AGNs. We do not plot the arrow along the W3-W4 since the extinction has a negligible effect in this case. Points as in Fig. 1.

3 AGN EMISSION AND WISE COLOURS

Even if the RL NLS1 are broadly clustered around the region expected for a power-law (PL) spectrum (with a spectral index $\alpha_{IR}$ ranging from $\sim 0.5$ to $\sim 1.5$), many departures from this region are also observed: some sources occupy the region above this line (towards redder W1-W2 colours) while others occupy a region bluer in W1-W2 and redder in W2-W3.

If the WISE emission of these RL NLS1 were totally dominated by the non-thermal jet we would expect a power-law or a broken power-law spectral shape. In Fig. 2 (left) we show the region on the W1-W2 vs W2-W3 plot where we expect to find a source whose IR spectrum is described by a broken power-law with a slope before the break ranging from 0.5 to 1 and a slope after the break of 1.5 and with the position of the break varying within the WISE bands (dark blue shaded area). As clear from Fig. 2 (left), we expect that a source with a broken power-law spectrum would fall above the PL line. Several sources are actually found in this region although the majority of them seem to be much “redder”, in terms of W1-W2 colour, than what is expected from a broken power-law.

In principle a significant level of extinction could change the position of a source with a power-law spectrum moving it away from the expected region, towards redder values of W1-W2 and W2-W3. However, since these sources are, by definition, type 1 AGNs, i.e. objects where both the AGN continuum and the broad emission lines are visible in the optical spectrum, the extinction is not expected to have an important impact on the mid-IR colours (e.g. see Mateos et al. 2015). In the upper-right side of both panels of Fig. 2 we indicate with an arrow the expected effect of an extinction of $A_V=2$ mag at the mean redshift of the sample ($<z>=0.36$). An $A_V$ of 2 magnitudes is the maximum expected for type 1 AGNs as discussed, for instance, in Caccianiga et al. (2008).

It is also possible that part (or the totality) of the observed IR emission is produced by the radio-quiet component of the source (i.e. the dusty torus) and not by the non-thermal jet. Indeed, the presence of this component is expected and it has been revealed in many radio-loud AGN and blazars (e.g. Malmrose et al. 2011; Raiteri et al. 2014; Gurkan, Hardcastle & Jarvis 2014; Castignani & De Zotti 2015). In Fig. 2 (left) we plot the position of 3 radio-quiet type 1 QSO templates 4 (from Polletta et al. 2007) in the range of redshift between

---

3 It should be considered that the AllWISE catalogue, that we are using in this work, has been produced by combining all the data from both the WISE cryogenic and post-cryogenic survey phases, the latter being carried out only in the W1 and W2 bands. Therefore, the periods over which the images have been collected and combined are different for the 4 bands.

4 These templates have been derived by Polletta et al. (2007) by combining the SDSS quasar composite spectrum and rest-frame IR data of a sample of optically-selected type 1 QSOs observed in the SWIRE program. The 3 templates have the same optical spectrum but three different IR SEDs: a mean IR spectrum, obtained from the average fluxes of all measurements.
0 and 0.9 (the range of z of the sample, red solid lines). The regions occupied by these 3 templates lie above the PL line and reach redder W1-W2 values than the broken power-law, in particular for high redshift sources (z between 0.5 and 0.9). Notably, the source with the reddest value of W1-W2 (=1.34, J1348+2622) is also the object with the largest redshift in the sample (z=0.918). Only the TQS01 template can reach such a red W1-W2 colour that a broken power-law, instead, does not seem able to reproduce. We consider this as an indication that, at least in a number of objects, the mid-IR emission is probably mainly produced by the radio-quiet component (i.e. the torus) rather than the relativistic jet.

Finally, we consider also the possibility that both the dusty-torus and the jet emissions are present in the spectrum. To this end, we combine the 3 QSO templates with a power-law emission, at different values of redshift (from 0 to 0.9), varying the relative normalizations of the two components (light blue shaded area).

From the analysis of Fig. 2 (left) we conclude that the sources lying above the PL line in the W1-W2 vs W2-W3 plot could be explained either by a broken power-law emission, expected when the jet emission is dominant, or by a RQ AGN (i.e. torus) emission or by a combination of the two components. Only one object (J0849+5108) lies above the PL but in a isolated region toward blue W2-W3 values (W1-W2=0.931 and W2-W3=1.914). As said before, this is a highly variable source and, therefore, its position is not indicative of the actual IR spectral shape.

In ~10 cases, the objects fall well below the PL line and, therefore, their colours are not easily explained by a torus/jet emission nor by a combination of the two. The number of sources not explained by these models is even higher if we consider the longest wavelength magnitude (W4, at \( \lambda=22\mu m \)) in the diagnostic plot i.e. if we plot W1-W2 vs W3-W4 (Fig. 2 right). As before, we over-plot the expected regions followed by a power-law, a broken power-law and a RQ AGN component plus a power-law emission. From this figure it is clear that only few objects can be explained by these models while the large majority (~ 80-90%) lie well below the PL line thus requiring a different (very red) component. As described in the following section, the best candidate for the emission of this red component is the host galaxy.

4 THE EFFECT OF GALAXY DILUTION ON IR COLOURS

We consider here the effect of the combination of an AGN plus the host galaxy emission on the WISE colour plots. To this end, we use some representative templates of the SWIRE library [Polletta et al. 2007]. Specifically, we use an early-type galaxy ("Ell5" template), an Sc galaxy ("Sc" template) and a starburst galaxy ("M82" template, Fig. 3). We start from a galaxy template and add a PL with different slopes and varying the relative AGN/galaxy normalization. In Fig. 3 we show the predicted effect of the host galaxy dilution on a power-law emission. An early-type host is expected to move the AGN colours towards the left/bottom side of the plot i.e. it is expected to produce bluer colours in both W1-W2 and W2-W3 (W3-W4) values as it gets more and more important. A starburst host, instead, is expected to make the W1-W2 values bluer than the power-law while both the W2-W3 and the W3-W4 colours become redder, thus bringing the object on the right-most side of the plot. Other starburst templates show a similar behaviour. This is the effect of the strong IR emission of the starburst component that becomes more and more important in the W3 (and W4) bands.

In Fig. 4 we also show the position of SDSSJ143244.91+301435.3, a RL NLS1 discussed in Caccianiga et al. (2014), whose SED has revealed the presence of a star-forming host galaxy with a SFR of 50 M\( _{\odot} \) y\(^{-1} \). In order to correctly reproduce the infrared SED (in particular the W4 photometric point) of this object we used the M82 template by Polletta et al. (2007).

Fig. 4 (left) shows that the host galaxy may be contributing significantly to the mid-IR emission in a number (10) of sources of the sample, i.e. those objects that occupy the region below the PL line. For the sources just below this line the contribution from the host galaxy in these WISE bands is not enough to distinguish the type of the host galaxy. In ~4 cases, instead, the very red W2-W3 colours seem to favour a star-forming host galaxy. We note that the position of SDSSJ143244.91+301435.3 on this plot does not clearly indicate a star-forming host galaxy. Indeed, as discussed in Caccianiga et al. (2014), the strongest indication for a M82-like host galaxy comes from the W4 band (22\( \mu m \)) which shows a clear excess. Fig. 4 (right) shows that using the W4 filter we can better discriminate between the different types of host galaxy. In particular, the mid-IR colours of the 22 sources with W3-W4>2.5 (like SDSSJ143244.91+301435.3) can be explained only by combining the AGN emission to a starburst galaxy host.

In order to better show the effect of the host galaxy on the observed spectrum we report in Fig. 5 the average UV-to-mid-IR SED of the NLS1 of the sample divided according to the value of W3-W4 colour (greater than 2.5 or lower than 2.3, in order to keep more separated the two groups). The average SEDs have been cre-
Figure 4. The effect of the host galaxy emission on a power-law spectrum, in the WISE colours plots (W1-W2 vs W2-W3, left, and vs W3-W4, right). The 3 regions between the long-dashed/short-dashed/point-dashed lines represent the expected paths of a combination of power-law plus a galaxy template taken from the SWIRE library (M82, Sc and Ell5 respectively, Polletta et al. 2007), varying the relative intensity of the two components, the power-law slopes (ranging from 0.5 to 1.5) and the redshift of the source ($\pm \sigma = \pm 0.2$ from the mean value of $z$). Note that the limits are different from those of Fig. 2 in order to better show the different paths produced by different host galaxies. Symbols and arrows as in Fig. 2. The blue star indicates the position of SDSSJ143244.91+301435.3, a RL NLS1 studied in detail by Caccianiga et al. (2014) and whose SED is suggestive of the presence of a starburst host galaxy.

Figure 5. Average UV to mid-IR SED of the RL NLS1 in the sample divided according to the W3–W4 colour. Red points represent the average values of Log($L_\lambda$) in each bin of Log($\lambda$) while the shaded area represents the region including 68% of points. The thick black line is a model composed by a reddened (the $A_v$ value is indicated in the label) AGN template (QSO1 from Polletta et al. 2007) plus a galaxy template: in the left panel an early-type galaxy template (Ell5) is used while, in the right panel, we adopt a starburst galaxy template (M82).
ated by normalizing each rest-frame SEDs at 4 μm and computing the average value of \( \log \lambda L_\lambda \) in bins of \( \log \lambda \). The grey area reports the region including 68% of points. The data used to produce these SED are taken from [Foschini et al. 2015] and include, besides WISE photometry, data from Swift/UVOT observations and from existing public surveys like SDSS (DR9, Ahn et al. 2012), 2MASS (Cutri et al. 2003) and USNO-B (Monet et al. 2003).

To correctly interpret the shape of these average SEDs we model them with the sum of a galaxy and a QSO template, varying the relative normalization, the amount of nuclear extinction and the host morphology (see [Ballo et al. 2014] for a more detailed description of the procedure). We consider different combinations of extinctions and galaxy/AGN templates and we find that templates with a low IR emission (early-type/Sc galaxies) are able to describe the observed average SED of the objects with bluer W3-W4 colours (left panel) while these templates systematically fail in reproducing the observed average SED of the objects with redder W3-W4 data points in the average SED of sources with redder W3-W4 (right panel). In this latter case, instead, a starburst galaxy template, like M82, is more suited to reproduce the steep increase of the data points towards longer wavelengths.

We note that the two average SEDs show some differences also in the UV/optical part. We can explain this difference with a different (average) extinction level. While to model the average SED of the sources with a blue W3-W4 colour we have to apply only a small level of extinction (A_V=0.1 mag), in the case of the red W3-W4 objects, we need a higher value of A_V (0.35 mag). The explanation of this result could be related to the enhanced presence of dust in highly star-forming galaxies with respect to less star-forming galaxies (see e.g. [Buat et al. 2002] and [Domínguez et al. 2013]).

5 JET OR STAR-FORMATION?

So far, we have focused our analysis on the UV to mid-IR data and, in particular, on the mid-IR colours. From these data we have inferred the presence of a star-forming/stellar host galaxy in at least half of the RL NLS1 in the sample. Since an intense SF is expected to produce an important emission also in the radio band it is possible that the radio luminosities observed in these sources are in part contaminated by the SF activity. In principle, it is even possible that a high SFR can explain the totality of the observed radio emission. This would be an unexpected result, since the sample under investigation is composed by objects with large radio-loudness parameters and, in some cases, a flat radio spectrum. These properties are usually considered as strong indications that the radio emission is likely produced by a relativistic jet pointing towards the observer (and, thus, relativistically beamed).

Since jet-dominated objects and star-forming galaxies have significantly different radio-to-mid-IR flux ratios, it is interesting to compare this parameter computed for the RL NLS1 to the values usually observed in jet-dominated AGN (i.e. blazars), from the one hand, and to the values observed in star-forming galaxies, on the other hand.

To quantify the radio-to-mid-IR flux ratios we use two equivalent parameters. The two point spectral-index, defined between 1.4 GHz and 22 μm (rest-frame) as:

\[
\alpha_{1.4}^{22} = \frac{\log(S_{1.4\text{GHz}}/S_{22\mu m})}{\log(v_{1.4\text{GHz}}/v_{22\mu m})}
\]

which is typically used in blazars studies, and the parameter q22 defined as:

\[
q_{22} = \log(S_{22\mu m}/S_{1.4\text{GHz}})
\]

The radio-to-mid-IR indices for the 37 RL NLS1 in the sample detected in the W4 band are reported in Fig. 6. For comparison, we also report the distribution of \( \alpha_{1.4}^{22} \) for a sample of 430 blazars with a quasar spectrum (Flat Spectrum Radio Quasar, FSRQ) extracted from the BZCAT ([Massaro et al. 2005]) and detected with high significance (S/N>10) in all the WISE filters. To help the comparison, this latter histogram has been re-normalized by a factor 10. We also indicate the typical range of radio-to-mid-IR values observed in the infrared galaxies reported by [Rieke et al. 2009]. In particular, we report the observed range of q24, a quantity similar to q22 but defined at 24 μm instead of 22 μm observed in the infrared galaxies is also indicated (light blue region, [Rieke et al. 2009]).

Figure 6. Distribution of the two-point spectral index between radio (1.4 GHz, rest-frame) and mid-IR (22 μm, rest-frame) of the RL NLS1 (blue histogram) and of blazars (BZQ) in the BZCAT (black shaded histogram). This latter histogram has been re-scaled by a factor 10 to facilitate the comparison. The flux densities have been K-corrected assuming a slope of 0 in the radio and using the observed IR slope between 12 and 22 μm. The filled blue histogram shows the RL NLS1 detected in the gamma-ray by FERMI. The dashed red histogram includes only the red (W3-W4>2.5) objects. The top axis reports the values of q22. For comparison, the typical range of q24 (defined at 24 μm instead of 22 μm) observed in the infrared galaxies is also indicated (light blue region, [Rieke et al. 2009]).
ponent in the radio band (while in the mid-IR different emission could be present, including the dusty torus and/or the host galaxy). In sources with $\alpha_{1.4}^{22} < -0.25$ (i.e. $q_{22} > 1$) the SF activity may be contributing significantly to the observed radio emission. This is likely true, for instance, in the sources with red W3-W4 colours (dashed red histogram), that are the majority in this interval of $q_{22}$ values. The most obvious interpretation for the objects showing intermediate values, instead, is a combination of jet and SF (plus the dusty torus, in the mid-IR).

In support to the hypothesis that the relativistic jet is dominant in sources with steep $\alpha_{1.4}^{22}$ values we note that 6 out of the 15 RL NLS1 with $\alpha_{1.4}^{22} > 0$ (i.e. 40%) are detected in gamma-rays by FERMI (filled histogram in Fig. 6), something that is usually considered as an indication for the presence (and the dominance) of a relativistic jet, while only one object (J1102+2239) out 22 with $\alpha_{1.4}^{22} < 0$ (5%) is a FERMI source. The dominance of the relativistic jet in 4 of the FERMI detected RL NLS1 with $q_{22}>0$ (J0324+3410, J0849+5108, J0948+0022 and J1505+0326) has been recently quantified also by Angelakis et al. (2015) by means of a systematic monitoring in the radio and millimetric bands.

This confirms the presence and the importance of the relativistic jet in the sources with a positive value of $\alpha_{1.4}^{22}$ while it seems to suggest that other mechanisms are at work in addition (or instead of) to the relativistic jet in most of the remaining sources. It is worth noting, however, that a low value of $\alpha_{1.4}^{22}$ (or a high value of $q_{22}$) does not necessarily exclude the presence of a jet as demonstrated by the detection in gamma-rays by FERMI of one of the objects with a high value of $q_{22}$ ($q_{22}=1.34$, J1102+2239)\(^1\). Another example is the sources J1227+3214 that, in spite of a large $q_{22}$ value ($=1.29$), has an inverted radio spectrum ($\alpha_{22}=-1.04$, Foschini et al. 2015) something that suggests a non-thermal origin of the radio emission (or at least of a fraction of it). It should be considered that variability can play an important role in determining the properties of a source at different wavelengths, including its position within the histogram of Fig. 6 during high activity periods, a source may appear as jet-dominated in many (if not all) frequencies, showing for instance a flat radio spectrum, a strong gamma-ray emission or a high radio-to-mid-IR flux ratio, while, during low activity periods, the signs for the presence of the jet can be hidden by the RQ AGN emission or even by the host galaxy light. For all these reasons, simultaneous multiwavelength monitoring campaigns, together with radio follow-ups, in particular at VLBI resolution, are fundamental to disentangle the different components and establish their relative importance at different wavelengths.

6 ESTIMATE OF THE STAR-FORMATION RATE

In this section we want to quantify the intensity of the star-formation at least in those sources where the mid-IR colours are suggestive of the presence of a starburst host. Specifically, we consider here only the 22 sources with a red W3-W4 colour (W3-W4>2.5). To limit the contamination due to the AGN nucleus (either the dusty torus or the jet component) we analyse here the longest wavelength WISE band (W4 at 22µm) since, according to the results previously discussed, this is the band where the star-forming nature of the host galaxy seems to emerge more clearly.

We first compute the 22µm luminosities ($L_{22}$). We derive the 22µm flux densities from the W4 magnitude\(^6\) and applied a K-correction using the spectral slope computed between 12 and 22µm (observed frame) fluxes. The computed 22µm luminosities of the sources range between $10^{10}$ to $10^{12}$ L$_\odot$ with a large fraction (76%) of objects with $L_{22}\mu m > 10^{11}$ L$_\odot$.

In order to derive an estimate of the SFR in these sources we can use the relation presented in Rieke et al. (2009) between SFR and $L_{22}\mu m$ (their eq.10 and eq.11). However, since the $L_{22}\mu m$ luminosity is likely contaminated by the AGN, in particular the dusty torus component, we have to apply a correction. To estimate the importance of the AGN emission at 22µm we proceed as follows.

Jet contribution. We estimate the contribution from the jet starting from the radio flux density measured at 1.4 GHz, assuming the average value of the $\alpha_{1.4}^{22}$ observed in the blazars (FSRQ) of the BZCAT catalogue ($\alpha_{1.4}^{22}=0.27$, see Fig. 5) and subtract it from the observed flux density at 22µm (rest-frame). For the 2 objects that have $\alpha_{1.4}^{22}>0.27$ the estimate of 22µm due to the galaxy is not possible and we exclude them from the analysis. For the sources with radio-to-mid-IR flux ratios similar to those observed in IR galaxies ($\alpha_{1.4}^{22}<0.25$), the correction for the jet emission is negligible (<1%) and has no impact on the final results. As discussed in the previous section, in these sources even the radio emission could be mainly (or totally) attributed to the star-formation activity.

Torus contribution. We estimate the contribution from the torus using the flux densities at 4.6µm (rest-frame) and assuming

\[^6\]Interestingly, this source was indicated by Foschini et al. (2015) as possible outlier in the gamma-ray/radio correlation.

\[^7\]For this conversion we assume an IR spectral slope of 1.

\[^8\]For the K-correction we use here, for each source, the observed slope computed between 3.4 and 4.6 µm.
that this is entirely produced by the AGN (jet and torus). This is a reasonable assumption since, as discussed in the previous sections, in the W1 and W2 filters we are probably preferentially observing the AGN emission (see also the average SEDs of Fig. 5). This is also consistent with what has been recently found by Mateos et al. (2015) studying the mid-IR properties of a sample of X-ray selected AGN. If also the host galaxy is contributing to the 4.6 μm emission (see also the average SEDs of Fig. 5). This is reasonable assumption since, as discussed in the previous sections, the estimate of the 22 μm luminosities of the host galaxies (see text for a description). In addition to this uncertainty it should be considered also the one related to the SFR-L(24 μm) relation (about ~0.2 dex, Rieke et al. 2009). Col. 4: logarithm of the 22 μm-to-1.4GHz flux density ratio; col. 5: W1-W2 colour; col. 6: W3-W4 colour; col. 7: radio spectral slope (Sν ∝ να) from Foschini et al. (2015).

Table 2. Estimates of the star-formation rate for the sources with W3-W4>2.5 and with α22 μm < 0.27, based on the 22 μm luminosities corrected for the AGN contribution (see text for details). Col.1: source name; col.2: logarithm of the SFR derived from the 22 μm luminosity; col.3: uncertainty interval on the SFR that takes into account only the errors on the estimate of the 22 μm luminosities of the host galaxies (see text for a description). Col. 4: logarithm of the 22 μm-to-1.4GHz flux density ratio; col. 5: W1-W2 colour; col. 6: W3-W4 colour; col. 7: radio spectral slope (Sν ∝ να) from Foschini et al. (2015). The SFR of these 20 objects are above ~10 M⊙ yr⁻¹ and, in several cases, larger than 100 M⊙ yr⁻¹, similarly to what is usually observed in Luminous Infrared Galaxies (LIRG) or even in UltraLuminous Infrared Galaxies (ULIRG, Sanders & Mirabel 1996). This result confirms and quantifies what we have inferred from the analysis of the mid-IR colours, i.e. the presence of an intense star-forming activity in at least half of the RL NLS1 in sample.

We finally note that a SFR estimate for the RL NLS1 with W3-W4<2.5 would not be reliable since the evidence of a significant contribution of a star-forming host galaxy to the emission at 22 μm is not clear. Running the analysis described above on the blue objects, we find that, on average, only a small fraction (~8%) of the observed 22 μm luminosities can be due to the host galaxy the remaining fraction being produced by the torus (56%) and by the jet (36%). The estimate of the 22 μm luminosity due to the host galaxy (and therefore the SFR quantification) depends too critically on the starting assumptions on the α22 μm of the jet and on the IR spectral shape of the dusty torus to give reliable results. The only stable quantities that we can derive are the upper limits on the SFR based on the total observed 22 μm luminosities. These values do not exclude the presence of an intense SFR (> 10 M⊙ yr⁻¹) also in the objects with W3-W4<2.5. From these upper limits alone it is not possible to understand whether the host galaxies of these AGN are intrinsically different from those observed in “red” RL NLS1 or, rather, their SF activity is simply hidden by a particularly strong nuclear light. We have, however, other pieces of information that can help to distinguish between these two hypotheses.

In Fig. 5 we have presented the average SEDs of red (W3-W4>2.5) and blue (W3-W4<2.3) objects, that clearly show different shapes at λ >10 μm. While the average SED of the red objects requires the presence of an M82-like template to be correctly re-
produced, the average SED of the blue objects can be modelled using an Sc or E115 template. An M82 template would over-predict the emission at $\lambda > 10\mu$m. We note that the normalization of the host galaxy template is quite well constrained in the spectral region around $\sim 1\mu$m (rest-frame). This suggests that the blue objects are hosted, on average, by different types of host galaxy.

In order to assess whether there are differences also in the luminosities of the AGN (either the radio-quiet or the jet component) between red and blue objects we can compare the average luminosities at 4$\mu$m, where the torus emission is expected to dominate, and in the radio band. At 4$\mu$m the average values are only marginally different, with the blue objects being about 30% more luminous than the red ones. Even in the radio band we do not have evidence that the jets in the blue objects are more luminous than the jets present in the red sources. Rather, the average 1.4 GHz power of blue objects is a factor $\sim 1.6$ fainter than in red objects. The average 22$\mu$m luminosity, instead, is significantly different between the two groups of sources, where the red objects are almost a factor 2 more luminous that the blue sources.

Overall, these numbers seem to indicate that the lack of a clear detection of the host galaxy in the blue objects is not due to a more luminous radio jet and/or AGN (radio-quiet) but, rather, to a less luminous 22$\mu$m emission, i.e. a less important star-forming component at work in these sources. As explained above, the upper limits on the SFR are in any case large so we cannot exclude the presence of an intense SF also in these sources but, on average, their activity, if present, seems to be less intense than the one observed in the host galaxies of the red RL NLS1. This picture needs a confirmation through an accurate follow-up (in particular of the blue RL NLS1) in the mid-IR or in the far-IR spectral region, where the maximum output of the SF activity is expected.

7 CONCLUSIONS

We have analysed the mid-IR colours of a sample of 42 RL NLS1 using WISE data with the aim of quantifying, for the first time, the star-forming activity in the galaxies hosting this class of AGNs. The sources cover the redshift interval from 0.06 to 0.92. Thirty-seven objects are detected in all the 4 WISE bands. In order to understand the origin of the mid-IR emission in these sources we have compared their positions on different diagnostic plots with those expected from a combination of AGN and host galaxy templates. The results can be summarized as follows:

- In general, the RL NLS1 of the sample occupy a region in the W1-W2 vs W2-W3 plot (commonly used in the literature) that is typical of emission line AGN, both radio-quiet and radio-loud.
- WISE colours can be reproduced by a combination of AGN and host galaxy emission, the relative importance of the two components depending strongly on the band under consideration. While the emission from 3.4$\mu$m up to 12$\mu$m (observed frame) of most (3/4) of the sources can be explained by the AGN alone (either the relativistic jet, the dusty torus or a combination of the two), at 22$\mu$m the emission usually requires the (red) contribution from the host galaxy.
- Twenty-two sources show very red W3-W4 colours (>2.5) that can be explained only by assuming the presence of a young and “active” host galaxy, i.e. a starburst galaxy similar to M82. In the remaining cases, the intensity of the AGN emission in the mid-IR bands does not allow to unambiguously assess the type of host galaxy.
- The 22$\mu$m luminosities of the NLS1 detected in W4 are typically above $10^{11}$ L$_\odot$. We have used these luminosities, corrected for the AGN contribution, to estimate the SFR for 20 out of the 22 sources with W3-W4>2.5. The computed values of SFR range between 10 and 500 M$_\odot$ y$^{-1}$. These values are similar to those observed in LIRG or even in ULIRG (Sanders & Mirabel 1996). For the sources with W3-W4<2.5 the presence of a star-forming host galaxy cannot be excluded although the SFR is expected to be, on average, lower than in red sources.
- Although the sample studied here has been designed to include NLS1 with a relativistic jet (possibly pointing towards Earth), by means of a selection of sources with a large radio-loudness parameter (radio-loudness parameter >10) and, preferentially, a flat radio spectrum ($\alpha_R < 0.5$, see Foschini et al. 2013 for details), our analysis shows that in the mid-IR the jet is not necessarily the dominant component, even in sources that have been detected in gamma-rays by FERMI. In particular, we have estimated that, on average, at 22$\mu$m only $\sim 20\%$ of the luminosity of the sources with W3-W4>2.5 comes from the jet, the remaining part being emitted by the dusty torus and by the host galaxy.
- Even at radio frequencies (1.4 GHz) the emission of a number (~10) of sources in the sample, i.e. those with high mid-IR-to-radio luminosity ratios, is not necessarily due to the jet but it is likely produced, in part or entirely, by the SF activity.

In conclusion, our analysis has shown that RL NLS1 are often associated to “active” host galaxies, with SFR in the typical range of LIRG/ULIRG sources. Therefore, from this point of view, RL NLS1 are more similar to RQ NLS1 than to radio-loud AGNs with broader emission lines, usually hosted by “passive” elliptical galaxies. These results support the idea that NLS1, both RQ and RL, are systems in the early phase of their evolution, when the host galaxy is experiencing a high level of star-forming activity and, at the same time, the central super-massive BH is rapidly accreting and building up mass. Studying the properties of these sources and their differences with respect to the other radio-loud AGNs will help us to understand the role of relativistic jets in the AGN/galaxy evolution and to unveil any possible form of feedback (either positive or negative). To this end, simultaneous follow-ups, both in the mid-IR and in the radio, are mandatory in order to accurately disentangle the different components at work in these active nuclei and to study their possible interplay.

ACKNOWLEDGMENTS

We thank the referee for useful comments that improved the paper. This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration.
