BACKGROUND The authors presented their experience with a case of repeat thrombectomy in a 93-year-old patient who showed a favorable outcome after recurrent large vessel occlusion treated with emergency mechanical thrombectomy.

OBSERVATIONS Mechanical thrombectomy has been proven to be effective in treating large vessel occlusion types of ischemic stroke. Most of the patient populations involved in the thrombectomy-related studies were younger than 80 years. In addition, recurrent mechanical thrombectomy is not a common procedure in clinical practice. This unusual case demonstrated the potential to achieve a favorable outcome with thrombectomy even in a patient older than 85 years with recurrent large vessel occlusion.

LESSONS There can be a favorable neurological outcome after one or repeat thrombectomies for geriatric patients older than 90 years, and age should not be a deterrent to treatment.

KEYWORDS ischemic stroke; mechanical thrombectomy; geriatric patients; large vessel occlusion

From 2015 to 2018, seven trials (MR CLEAN, REVA SCAT, ESCAPE, SWIFT PRIME, EXTEND-1A, DIFFUSE 3, and DAWN) provided evidence of increased functional independence without increasing the risk of death after the early performance of mechanical thrombectomy. Intravenous chemical thrombolysis and mechanical thrombectomy have become the gold standards for treating patients who experience acute ischemic stroke.

Despite its rarity, recurrent mechanical thrombectomy has been considered a relatively safe procedure. Bouslama et al. found no statistically significant differences in demographics, stroke severity, time from last known normal to puncture, reperfusion rates, hemorrhagic complications, good clinical outcomes, and mortality between patients who underwent repeat thrombectomy and patients who had a single thrombectomy. That finding reflected a favorable neurological outcome. The role of mechanical thrombectomy in patients older than 85 years has also been debated, given the overall risk of a worse outcome in this population. Recent studies, however, have shown that a patient population older than 85 years may still benefit from thrombectomy, especially with complete recanalization, despite the risk. We present a case study of a 93-year-old woman who showed significant improvement in functional outcome after each of the two thrombectomies she underwent.

Illustrative Case A 93-year-old woman with a past medical history of hypertension, hyperlipidemia, and gout presented with the acute onset of left-sided weakness and left-sided facial droop. She was last seen well at 1:00 PM, and her National Institutes of Health Stroke Scale (NIHSS) score upon arrival was 22. The patient received alteplase at 2:21 PM. A right middle cerebral artery (MCA) M1 occlusion was revealed on computed tomography angiography (CTA) and diagnostic cerebral angiography (DCA) (Fig. 1A). CTA showed mild calcified atherosclerotic plaques at the carotid bifurcation bilaterally but no significant intracranial atherosclerosis.

The patient underwent successful right M1 mechanical thrombectomy and had a Thrombolysis in Cerebral Infarction (TICI) score of 3 at 4:15 PM (Fig. 1B). Her premorbid modified Rankin Scale (mRS) score was 0. Magnetic resonance imaging (MRI) of the brain showed

ABBREVIATIONS CT = computed tomography; CTA = CT angiography; DCA = diagnostic cerebral angiography; MCA = middle cerebral artery; MRI = magnetic resonance imaging; mRS = modified Rankin Scale; NIHSS = National Institutes of Health Stroke Scale; TICI = Thrombolysis in Cerebral Infarction.

restriction diffusion of the right basal ganglia without evidence of hemorrhage. Her discharge NIHSS score was 0. The etiology of the stroke was concluded to be cryptogenic after thorough stroke workup, including transesophageal echocardiography with bubble study, thyroid function test, and lipid profile, which did not reveal significant abnormality. She was discharged with instructions to take aspirin 81 mg and atorvastatin 80 mg daily.

Fifty-two days later, at 10:27 AM, the patient presented with the acute onset of left-sided weakness and slurred speech. Her NIHSS score upon arrival was 8. The patient was last seen well at 3:00 AM and thus was not a candidate for chemical thrombolysis. Head computed tomography (CT) showed no acute infarct. CTA showed occlusion of the right proximal M2 superior division of the MCA. CT perfusion of the brain showed ischemic penumbra of 55 mL without an ischemic core in the respective vascular territory (Fig. 2A). She underwent mechanical thrombectomy at 12:10 PM with TICI 3 revascularization (Fig. 3). MRI showed small-to-moderate volume, right MCA territorial ischemic infarct with minimal petechial hemorrhage (Fig. 2B). Her NIHSS score at discharge was 0. Her collateral circulation assessment based on the CTA was overall good and was considered to have the following scores according to single-phase CTA collateral scores in acute stroke: Tan et al. = 2; Maas et al. = 2/3; Souza et al. = 2/3; Cristoforidis = 2; Miteff = 2; and ASPECTS = approximately 3.11–18

After her second stroke, a cardiac loop recorder was implanted. It did not reveal any evidence of dysrhythmia, which confirmed the diagnosis of cryptogenic stroke. The patient was started on apixaban 2.5 mg.

Discussion
Observations
The HERMES meta-analysis favored endovascular thrombectomy even in patient populations older than 80 years, noting that it significantly reduced disability at 90 days as compared to that in the standard medical treatment arm of the study.19 This meta-analysis included 198 patients with an age ≥ 80 years, and the rate of an mRS score of 0 to 2 at 90 days was 29.8% in the endovascular group and 13.9% in the control group (OR 3.68, 95% CI 1.95–6.92). However, the rate of an mRS score of 0 to 2 at 90 days in the endovascular group decreased with advancing age: 50 to 59 years, 50.0%; 60 to 69 years, 51.9%; 70 to 79 years, 43.1%; and ≥ 80 years, 29.8%. Therefore, this meta-analysis
suggested that age remained a strong independent negative predictor of outcome despite the treatment effect of mechanical thrombectomy.

Imahori et al. demonstrated significant differences in procedure times for endovascular treatment between patients whose age was ≥ 80 years and those whose age was < 80. They found that being 80 years or older was not a significant predictor for outcomes after mechanical thrombectomy (42% vs 57%, respectively; p = 0.261) or death (8% vs 5%, respectively; p = 0.653), whereas complete recanalization was an influential predictor with a positive outcome, particularly in those 80 years or older with complete recanalization (mTICI 3). Recurrent mechanical thrombectomy is generally not contraindicated; in fact, it appears safe in properly selected patients with recurrent large vessel occlusion strokes. Bousslama et al. studied a group of patients who underwent repeat thrombectomy. Although none of the selected patients was more than 90 years old, they showed favorable outcomes without a significant increased risk of intracranial hemorrhage or significant increase in the risk of death.

Six of the 15 patients involved in the study had ipsilateral (same stream) repeat thrombectomies. At 90 days, the mRS score for 4 of the 6 did not show worsening, 1 showed improvement, and 1 had a worse mRS score after a third stroke. A recent study by Lee et al. also concluded that ipsilateral repeat thrombectomies produced a significantly better clinical outcome when compared to that with contralateral repeat thrombectomies (83.3% vs 16.7%, p = 0.027), but none of the patients was older than 90 years.

Lessons
Repeat mechanical thrombectomy is an uncommon procedure in clinical practice, and to our knowledge, this is the first reported patient older than 90 years with a good functional outcome after both interventions. Although the overall outcomes in such patient populations may be worse than in younger populations and first-time thrombectomy patients, the current literature supports an aggressive approach even in these groups. The limitations of this approach for geriatric patients are multifactorial, including stroke size, medical co-morbidities, operative and postoperative complications, and adverse effects of the secondary stroke prevention measures, which can further challenge the outcome. Further retrospective studies are necessary to analyze the benefits and challenges of performing thrombectomies in patients older than 90 years to build on the literature and find potential positive outcomes. Moreover, it is necessary to consider that as the aging population increases, more dynamic studies will be necessary to tend to these individuals.
