Speciation with ongoing homogenizing gene flow, later dubbed sympatric speciation, has been a fascinating and debated topic since Darwin proposed it. Here, we analyzed sympatric speciation of the spiny mouse, Acomys cahirinus, from Evolution Canyon I, Mount Carmel, Israel, revealed by whole-genome, methylome, and behavior comparisons. Mitochondrial phylogeny indicated that the tropical African Slope (AS) and temperate European Slope (ES) populations were sister taxa and shared a common ancestor. Based on the de novo chromosomal-level genome, we compared the genome and methylome of the two populations from EC I. We found clear-cut divergences between them based on both single nucleotide polymorphisms (SNPs) and structure variations (SVs). We identified 440 highly diverged regions and found olfactory receptors significantly divergent between slopes, suggesting prezygotic reproductive isolation. Furthermore, genes related to adaptation were enriched in immunity, temperature homeostasis in AS and energy, and cell cycle in ES. Population demographic modeling showed that the AS and ES populations split from the same ancestor with decreasing gene flow, implying sympatric speciation. Epigenetic methylation divergence preceded genetic differentiation and facilitated slope adaptation and sympatric speciation. We found a significant difference in activity onset in laboratory between the two populations, associated with the methylation divergence of circadian genes. We concluded that behavioral, genomic, and methylomic divergence substantiated sympatric speciation of Acomys from EC I in Israel, shown earlier transcriptomically.

Significance

Whether sympatric speciation (SS) is rare or common is still debated. Two populations of the spiny mouse, Acomys cahirinus, from Evolution Canyon I (EC I) in Israel have been depicted earlier as speciating sympatrically by molecular markers and transcriptome. Here, we investigated SS both genomically and methylomically, demonstrating that the opposite populations of spiny mice are sister taxa and split from the common ancestor around 20,000 years ago without an allopatric history. Mate choice, olfactory receptors, and speciation genes contributed to prezygotic/postzygotic reproductive isolation. The two populations showed different methylation patterns, facilitating adaptation to their local environment. They cope with abiotic and biotic stresses, due to high solar interslope radiation differences. We conclude that our new genomic and methylomic data substantiated SS.
divergent selection (19). Genomic regions with a low recombination rate will be more differentiated, especially after long-term differentiation accumulation (20). Sex pheromones are mate-recognition signals and will help animals find the right mate partner (21). Olfactory receptors (ORs) and mate choice reinforce prezygotic reproductive isolation (21). Other speciation genes, identified in many cases of speciation (22, 23), contribute to postzygotic reproductive isolation (22, 23).

Ernst Mayr argued that geographical barriers were a must for speciation (24), and this hypothesis dominated for many years, although he changed his mind because of the accumulated evidence (25). Recently, speciation with gene flow is also proved to be possible by both theoretical models and empirical studies (1, 4, 9, 16, 26, 27). In these studies, physical barriers are absent, and natural selection is the driving force for divergent adaptation and speciation, based on NGE innovations (12). SS was proposed by Darwin about 160 y ago (28), and it occurred in a freely mating population, driven by natural selection, like host switching (29), divergent phenology (30), and resource division (4). SS is interpreted speciation (33). Some methylation events could contribute to postzygotic reproductive isolation (22, 23), complementing the gaps in our assembly, respectively (SI Appendix, Fig. S2), indicating completeness of the assembly. We anchored 108 (90%) contigs with a total length of 2.26 Gb (99.78%) onto 19 pseudochromosomes (SI Appendix, Tables S1 and S3 and Fig. S3). Finally, we obtained a high-quality A. cahirinus reference genome (Table 1 and Fig. 1A).

DNA methylation was supposed to play essential roles in adaptation and speciation (31–33), and it could extend the Bateson–Dobzhansky–Muller model to a broader spectrum to interpret speciation (33). Some methylation events could increase fitness, and thus, some loci were fixed and spread to the entire population, resulting in novel morphology, physiology, behavior, and ultimately reproductive isolation (34). Methylation, as plastic variation and facilitating adaptation to short-term environmental changes, may diverge before any genetic differentiation and could occur during the early age of speciation (34). Thus, population methylation comparison could help us understand how it initiates population divergence, facilitates reproductive isolation, and maintains species boundaries (34).

EC I was proposed as a natural evolutionary laboratory in 1990 in lower Nahal Oren, Mount Carmel, Israel (32°24′N, 34°58′E). Together with Evolution Plateau (32°52′N, 35°33′E), both have been identified as hot spots of SS, based on microclimatic and geological-edaphic microsites demonstrated the commonality of SS as a realistic model in microsites divergent ecologically with reproductive isolation pre- or postzygotic, or both (13).

Gene Families and Phylogenetic Analysis. To investigate the phylogeny of A. cahirinus, we constructed a phylogenetic tree based on 6,285 single-copy orthologous genes of 13 mammal species (Fig. 1B). The phylogenetic tree of the four Acomys species (A. russatus, A. percivali, A. cahirinus, and A. kempii) based on a mitochondrial genome is consistent with that based on the nuclear genome (Fig. 1B, SI Appendix, Fig. S6, and Dataset S1). However, we observed a phylogenetic discordance that A. cahirinus showed a closer relationship with A. kempii rather than A. russatus (Fig. 1B) in the concatenated tree, while A. cahirinus is closer to A. russatus in the coalescent tree (SI Appendix, Fig. S5). The proportions of the three topologies on this node were ~39%, ~35%, and ~26%, respectively (Fig. 1B and C and SI Appendix, Fig. S7). Therefore, quantifying introgression via branch lengths (38) was used to test whether incomplete lineage sorting (ILS) or introgression contributed to the discordance. Results revealed that ~73% (~46%) with Bayesian information criteria, BIC filtering) of discordant loci were caused by ILS (SI Appendix, Table S6). We conducted a collinearity analysis among the four Acomys species, and the results showed that A. percivali and A. kempii had high collinearity with large syntenic blocks (SI Appendix, Fig. S8). Nevertheless, extensive chromosome breaks were found in A. russatus (SI Appendix, Fig. S9). A. cahirinus diverged from its common ancestor ~0.2 million years ago (Mya) (Fig. 1B). Out of the 16,914 gene families in the A. cahirinus genome, we
Additionally, SVs and copy number variations (CNVs) were used to explore population genetic differentiation, all results of which indicated that AS and ES had an obvious genetic divergence (Fig. 2). We used principal component analysis (PCA), and structure analysis to construct population structure and estimate genetic parameters, including recombination rates, linkage disequilibrium (LD), FST, dXY, and nucleotide diversity, were calculated (SI Appendix, Fig. S17 and Table S11). The recombination rate was significantly higher in AS. The nucleotide diversity was positively correlated with the recombination rate in both populations (AS correlation: 0.1885, P = 0; ES correlation: 0.1157, P = 0, Spearman correlation coefficient). The LD decayed to half maximum within 50 kb, and AS showed a sharp decay compared to ES (SI Appendix, Fig. S18). Population demography was estimated using pairwise sequentially Markovian coalescent (PSMC). Similar fluctuations of effective population size (Ne) were observed in AS and ES (Fig. 2E). There were two population declines during two glaciations: Saalian interglacial (130–300 kya) and the last glacial maximum (LGM) around 20,000 y ago (Fig. 2E). The Ne of the two populations started to increase at ~70,000 y ago and reached a peak around 25,000 y ago. We then simulated six speciation models: speciation with no gene flow, early gene flow, recent gene flow, split model, equal gene flow, and decreasing gene flow, a scenario meeting SS (SI Appendix, Fig. S19). The best-fit model by a difference in Akaike information criterion values of two orders of magnitude suggested that AS and ES diverged with decreasing gene flow from ancient, larger gene flow (~4 × 10−5) before 2.4 kya to the current, smaller gene flow (from AS to ES: ~3 × 10−7, and from ES to AS: ~2 × 10−7). The gene flow from AS to ES is larger than the opposite, and AS showed a larger population size (Fig. 2F and SI Appendix, Table S12).

Genetic Divergence and Demographic History. We first constructed the mitochondria tree based on 13 coding genes extracted from each sample from EC I and one individual out of EC. Results showed that samples from EC I had a common ancestor (SI Appendix, Fig. S10). Whole-genome resequencing was performed on all individuals from the AS and ES populations located in EC I (SI Appendix, Fig. S11), and the clean reads were mapped to the reference genome assembled above. Sequencing depths for each individual ranged from 35,363 to 1,439 in AS populations, including 892 losses and 675 gains in ES, and 1,439 in AS containing 766 losses and 673 gains (SI Appendix, Table S10). Genetic parameters, including recombination rates, linkage disequilibrium (LD), FST, dXY, and nucleotide diversity, were calculated (SI Appendix, Fig. S17 and Table S11). The recombination rate was significantly higher in AS. The nucleotide diversity was positively correlated with the recombination rate in both populations (AS correlation: 0.1885, P = 0; ES correlation: 0.1157, P = 0, Spearman correlation coefficient). The LD decayed to half maximum within 50 kb, and AS showed a sharp decay compared to ES (SI Appendix, Fig. S18). Population demography was estimated using pairwise sequentially Markovian coalescent (PSMC). Similar fluctuations of effective population size (Ne) were observed in AS and ES (Fig. 2E). There were two population declines during two glaciations: Saalian interglacial (130–300 kya) and the last glacial maximum (LGM) around 20,000 y ago (Fig. 2E). The Ne of the two populations started to increase at ~70,000 y ago and reached a peak around 25,000 y ago. We then simulated six speciation models: speciation with no gene flow, early gene flow, recent gene flow, split model, equal gene flow, and decreasing gene flow, a scenario meeting SS (SI Appendix, Fig. S19). The best-fit model by a difference in Akaike information criterion values of two orders of magnitude suggested that AS and ES diverged with decreasing gene flow from ancient, larger gene flow (~4 × 10−5) before 2.4 kya to the current, smaller gene flow (from AS to ES: ~3 × 10−7, and from ES to AS: ~2 × 10−7). The gene flow from AS to ES is larger than the opposite, and AS showed a larger population size (Fig. 2F and SI Appendix, Table S12).

Genomic Islands Analysis. Genome-wide average divergence of the two populations, measured by FST, was 0.03, and 41% of

Table 1. Summary of the A. cahirinus genome assembly and annotation

windows showed zero $F_{ST}$ (SI Appendix, Fig. S20). As the divergence across the genome is heterogeneous (SI Appendix, Fig. S17), elevated $F_{ST}$ regions with $Z_{F_{ST}} \geq 4$ were identified as genomic islands, also known as highly diverged regions (HDRs). We got 1,142 HDRs with a mean size of 15,946 bp scattered across the genome (SI Appendix, Fig. S21). The total length of these regions was ∼18 Mb (∼1% of the genome). Furthermore, we observed a high $F_{ST}$ in HDRs compared to the simulated data with neutral coalescent under the best-fit model identified above ($P < 0.01$; SI Appendix, Figs. S19 and S22). We compared the differences between island and background regions and found most HDRs were characterized by reduced nucleotide diversity and recombination rate, elevated LD, and excess of low-frequency variants (reduced levels of Tajima’s $D$) (SI Appendix, Table S13). We further tested whether gene flow from the population outside the canyon could produce HDRs and contribute to speciation. We compared $\pi_3$ in HDRs with that in background regions, which revealed that there was no significantly elevated $\pi_3$ in HDRs ($P = 0.09$; SI Appendix, Fig. S23), rejecting the hypothesis of speciation caused by gene flow from a population outside the canyon.

The speciation-with-gene-flow model predicted that loci involved in speciation should be characterized by both high $F_{ST}$ and high $\delta_{XY}$ (39, 40). The HDRs with high $F_{ST}$, $\delta_{XY}$ and normal $\pi$ simultaneously were suggested to directly contribute to speciation (41). By contrast, continuing adaptive loci would be expected to have elevated $F_{ST}$ but not $\delta_{XY}$ (41). After combining the adjacent HDRs, we identified 440 windows, including 110 genes in total with elevated $\delta_{XY}$ ($P < 0.01$, Mann–Whitney $U$ test) and normal $\pi$ both in AS and ES compared to background regions (SI Appendix, Fig. S24A). Furthermore, we calculated $\pi$-diff for each window, and finally, we got 385 and 255 HDRs in AS and ES (SI Appendix, Fig. S25). In adaptive HDRs, we observed a reduced nucleotide diversity ($P < 0.01$, Mann–Whitney $U$ test) compared to the rest of the regions (SI Appendix, Fig. S26). Genes located in HDRs were recognized as HDR genes (Dataset S3). GO enrichment on genes under adaptation in AS was related to response to defense and inflammation (GO: 0031349, 0050729, 0039595, 0042129, 1902107), temperature homeostasis (GO: 0001659), and nervous system development (GO: 0051962). In ES, an OR (OR6K3) was selected, which was involved in temperature homeostasis (GO: 00001659) and cell cycle control. Furthermore, we scanned the ORs across the whole genome, methylated Cs mainly occurred in the cytosine-guanine (CG) format (72.6–77.3%), and only 0.6–0.9% were in the cytosine-H-guanine (CHG, H represented A, T, or C) context.
and 0.6–1% in the cytosine-H-H (CHH) context. The total number of differentially methylated regions (DMRs) was 28,636, with a total length of ~5.9 Mb, and the mean methylation level in DMRs in AS was higher than in ES (0.70 versus 0.64, *P* < 0.01; SI Appendix, Table S15). Considering all DMRs, 36.4% are located in the gene body (SI Appendix, Fig. S27). Based on the DMR regions, we estimated the mean percentage of Cs in each chromosome of each sample. The two populations showed two different methylation clusters in PCA (Fig. 3A). The methylation levels in transcription start sites (TSSs), gene bodies, 10 kb upstream, and 10 kb downstream were compared, and the average methylation level is significantly higher in AS than in ES (Fig. 3B). We observed low methylation levels in the TSS regions in AS and ES populations based on all genes (*P* < 0.01). We estimated the methylation levels in these four regions of the selected genes compared to the rest of the genes in AS and ES (Fig. 3D). We found a similar pattern in the two populations: an obvious fluctuation and higher methylation levels (*P* < 0.01) were
observed in selective sweeps. In the TSS region, nonselected genes showed an increase in comparison to selected genes. According to previous studies, methylation kept a negative influence on transposable elements (TEs). In this study, we divided TE into five classes: DNA transposons, LTR, SINE, LINE, and other classes. We compared the methylation levels between TE and non-TE regions and got the same results in AS and ES (Fig. 3C). Methylation is higher in TE regions, except in LINE ($P < 0.01$, Fig. 3C). Similar results were observed in each sample from two populations (SI Appendix, Fig. S28). Finally, DMRs located in the gene body and its 3-kb flanking regions were identified as DMR genes. We got 1,790 DMR genes based on the DMR regions with different levels of more than 0.2, and GO enrichment showed that genes were enriched in circadian wake/sleep rhythm (GO: 0042752, 0042745, 0007623), DNA damage (GO: 0006307, 0045739, 001022, 006282), lipid storage and usage (GO: 0019915, 0055088, 0046461, 0006638), renal system development (GO: 007200, 0001822, 0072703), and temperature homeostasis (GO: 1990845, 0106106, 0001659, 0120161) (Fig. 3E and Dataset S4).

**Daily and Circadian Sleep and Wake Activity Patterns of Two Populations.** To test whether differences existed in daily and circadian activity patterns of the two populations, we tested the circadian cycle ($\tau$) and the onset of activity time differences under 12L:12D laboratory conditions between the AS and ES populations. Two populations did show different activity patterns (Fig. 4A and B and SI Appendix, Fig. S29). In constant

---

**Fig. 3.** DNA methylation divergence across the whole genome between two populations. (A) PCA on CpGs between the AS and ES populations. (B) Methylation at TSS, gene bodies, and adjacent upstream and downstream regions in AS and ES. Red line and blue line represent AS and ES, respectively. (C) Differences in average methylation levels between TE regions (DNA, LINE, SINE, LTR, other classes) and background regions. Asterisk represents significantly elevated methylation levels compared to background regions ($P < 0.01$). (D) Differences in methylation between selected genes and nonselected regions. (E) DMR genes are associated with four functional enrichments, including DNA damage repair, circadian rhythm, kidney system development and liquid balancing, and lipid storage and usage.
darkness, samples from the AS had significantly longer τ values (average 23.85 ± 0.03 h, n = 8) compared to samples from ES (average 23.69 ± 0.11 h, n = 4, P = 0.05; Fig. 4D and SI Appendix, Table S16). In addition, the average center of gravity of samples in AS was significantly earlier than in ES (mean onset = 11.5 ± 0.1 h after lights onset in AS, 12.9 ± 0.1 h after lights onset in ES, P < 0.01; Fig. 4C and SI Appendix, Table S16).

Discussion

Phylogenetic Inference in Acomys. Gene flow, ILS, or both could lead to phylogenetic discordance (42). The discordance between A. russatus and A. percivali we observed was due to ILS (Fig. 1B and C). ILS could happen easily if the divergence happened in a short time (42, 43). The divergence of A. russatus and A. percivali occurred in a comparatively short time (Fig. 1B), which explains the incongruent phylogeny (Fig. 1B and C).

SS Inference in Acomys. The two spiny mouse populations from the EC I were described elsewhere, and they followed the criteria of incipient SS (26, 37). The robust selection of contrasting ecologies—including different temperatures, humidity, and solar radiation on the two abutting slopes—overrides gene flow, leading to divergent adaptation and speciation (16, 36). As the two slopes are so close, from 0 to 250 m, it supplies us with an optimal model for SS.

Population Structure and Genetic Diversity. A de novo genome was assembled with long-read sequencing (SI Appendix, Table S1) and generated the best-qualified chromosomal-level reference to date, which facilitated our genome research of this species. The assembled genome size is 2.29 Gb, which is a little larger than that estimated in the genome survey (SI Appendix, Fig. S1), but it is reasonable. The resequencing depth for each individual ranges from 19× to 42× of the genome, which is deep enough to identify reliable SNPs and SVs. In the neighbor-joining tree (Fig. 2A and B) and PCA (Fig. 2C and D) based on SNPs and SVs, respectively, the two populations from EC I were separated into two clear-cut clusters, and the individuals from the same microclimatic environment were grouped together (Fig. 2A and B). These analyses demonstrate that the divergent microclimate shaped the genetic divergence in both SNPs and SVs. This is congruent with our previous study using RNA-seq (26) and the study on the blind mole rat (1, 2), where the contrasting stresses drove the adaptive genome divergence. The PCA shows larger intrapopulation genetic variation, possibly because of the higher stress on the cool and humid (35, 36) ES slope, where the habitat is unfamiliar to dry-tropically originated Acomys.

In the ancestral estimation analysis, individuals from the AS population show the same genetic background. However, the ES population shows intrapopulation variations (SI Appendix, Fig. S12), possibly because of the different time migration from AS and the higher positive selection in ES (26). In the RNA-seq study, we found the same situation: the individuals from AS displayed the same ancestry, while the individuals from ES harbored different ancestral backgrounds (26). There are several individuals from ES that showed the same ancestral background.
as in AS, suggesting ancestry and gene flow from AS (SI Appendix, Fig. S12).

The mean LD was lower in AS than in the ES population, possibly because of the larger effective AS population size (Fig. 2F), and when the animals dispersed to the ES from the AS, gene flow or admixture could create LD. In addition, humid and cool stresses (26) in ES might select for the higher linkage disequilibrium in ES (SI Appendix, Fig. S18). Many evolutionary processes could influence the recombination rate, like environmental, molecular, and demographic factors (44). The significantly higher recombination rate in AS population also contributes to lower LD and higher genetic diversity (45). The recombination rate of the AS population is significantly higher than that of the ES population, which could probably generate more genetic diversity to help the population cope with the drought and the hot and high solar radiation stresses (35) on the AS (46).

Genomic Divergence and Olfactory Differentiation. Although continuous but decreasing gene flow between the AS and ES populations was inferred, the genes displayed substantial heterogenous genomic divergence (SI Appendix, Fig. S17). High-F_{ST} genomic islands with elevated d_{XY} and nonreduced genetic diversity (SI Appendix, Table S13) were reported to be involved in speciation; by contrast, high-F_{ST} and d_{XY} regions with reduced genomic diversity were supposed to be adaptive loci. The different food resources shaped the different metabolisms. The richer food supply on the ES meets the cellular development and the function of the energetics category, which could resist lower temperature in ES, congruent with that found in the RNA-seq study (26). Temperature homeostasis may contribute to resistance to the excessive temperature difference between day and night.

Mate choice could lead to fitness benefits, like increasing the number of offspring or being better at surviving and reproducing (47). Olfaction plays an essential role in mate choice, which will lead to reproductive isolation (48). ORs are known to be involved in chemical communication with the external environment, and their differentiation could contribute to mate choice and reproductive isolation (1). Regions of 147 ORs significantly diverged compared to the non-OR region (Fig. 2D), suggesting prezygotic isolation. Remarkably, two genes, ERR2 and SPAG8 (49, 50), related to speciation were identified at highly diverged regions.

Allochrony on a day, season, or year level could contribute to reproductive isolation and SS (51). In the present study, due to the chronological difference in the sunshine on the two slopes (AS earlier than ES), animals from the AS slope start activities 1 h earlier than those on the ES slope (Fig. 4). Correspondingly, genes related to the circadian sleep/wake cycle showed differential methylation (Fig. 4C). Although the 1-h chronological difference may not be enough for SS in mammals, it could be more common than we thought (51).

Demographic History. As a dry-tropically originated species, A. cahirinus colonized the hot, xeric savannoid AS, ECI more than 20,000 y ago. They dispersed to the cool, humid ES subsequently during the Natufian age, where the zoologist professor Georg Haas identified paleontologically a fossil Acromys in the Natufian of Um Usha cave, at the top of ES. He named it Acromys camaelensis (52). This is the living species we identified here genomically and methylonomically and, earlier, transcriptomically (27) and mitochondrially (37). The Ne of the two populations fluctuated simultaneously (Fig. 2E) presumably because they are sympatric and under the same macroclimate.

Two population declines (Fig. 2E) were observed during the Saalian and LGM periods. Either the interpluvial or the glacial periods could lead to a food shortage for Acromys, and low temperature is a strong stress for tropical-originated species.

Speciation patterns could be inferred from gene flow. In allopatric speciation, incipient species were isolated by physical barriers. Thus, no gene flow could be detected (SI Appendix, Fig. S23A). In secondary contact, very limited or no gene flow could be detected at the beginning stage, and later, gene flow increased (SI Appendix, Fig. S19C). In SS, sister species should diverge with decreasing gene flow without allopatric history (SI Appendix, Fig. S19E), and if the gene flow was blocked at the second stage (SI Appendix, Fig. S19B), it was also allopatric speciation. If populations were not diverging, stable gene flow is expected between lineages (SI Appendix, Fig. S19D) (14). The best-fit model strongly showed (SI Appendix, Table S12) that AS and ES populations started to split from the same ancestor 20,000 y ago. Decreasing gene flow (Fig. 2F) occurred between the two populations (SI Appendix, Table S12), which satisfies the SS scenario. The Ne of AS is larger than that of ES because the hot, dry, and savannoid environment is very similar to that in its origin, which is consistent with our field observation. The AS and ES populations contracted to about 42 k and 1 k, respectively, recently because of the last interpluvial climate.

Methylation Differentiation between the AS and ES Populations. The AS and ES populations showed significantly different methylation patterns (Fig. 3A), and they did show more complete separation than that based on SNPs (Fig. 2B and D), which is consistent with the previous report that methylation divergence precedes genetic differentiation and may initiate divergence between populations (53). Generally, the average methylation is higher in AS population in TSSs, 10 kb up- and downstream of genes, and in gene bodies (Fig. 3B), suggesting generally high stresses (54). Theory predicted that incipient species would show greater methylome differentiation than their corresponding genome divergence (34). In the present study, we did find more complete differentiation in methylene than in the genome (Fig. 2A). Methylated cytosines could transit to thymine by deaminating, leading to stable genetic differences in short evolutionary periods (55). TE were supposed to have substantial deleterious effects on the host genome, and their expression should be under control (56). In the present study, hypermethylation was also observed in regions with more TEs (Fig. 3C), which could maintain a stable genome and facilitate adaptation and speciation. Significantly higher CpG methylation was observed within selected genes (Fig. 3D), including gene bodies and 10 kb up- and downstream of gene bodies than the counterparts in nonselected genes, which is probably due to the selected genes being of great importance to adaptation and should be more stable, consistent with the previous study in the great tit (32).

Prenatal famine exposure has been proven to leave a DNA methylation signature in the genome and may affect biological growth and metabolism (57). We found DMR genes enriched in lipid storage (Fig. 3E and Dataset S4), possibly because of the food shortage during xeric summer (36). No water resources could be used in the arid AS environment during the no-rain summer, and only very limited water could be obtained from the snails (58). We found several GO items in DMR genes related to kidney development, and the capacity of the kidney to concentrate urea in the arid AS environment was
expected to be much stronger in order to protect the animals from losing too much water (59). The solar radiation in AS is 200–800% stronger than that in ES (36), and UV can create substantial damage to DNA and proteins and even lead to tumors (60). Damaged protein degradation and removal will improve the quality of proteome and maintain proper protein turnover, helping the cell cope with oxidative stresses (61), and could facilitate their adaptation to the stronger solar radiation in AS environment (26). DNA methylation was a mechanism to drive circadian clock plasticity (62). Interestingly, five GO items related to circadian sleep/wake cycle were obtained in DMRs (Dataset S4). This explains why the AS individuals are active 1 h earlier than in ES (Fig. 4).

In conclusion, the divergences of population genomes, ORs and speciation genes, and methylomes, together with the behavior allochrony, substantiated SS of Acomys in EC I, Israel. Remarkably, EC I is a hot spot of SS across life from bacteria to mammals (13).

Materials and Methods
All the experiments on the animals were approved by the Ethics Committee of Lanzhou University and University of Haifa. Genome sequencing was performed on HiSeq 2500 with PE 125 bp. Genome assembly was performed by NextDe-novo. Divergence time among species was calculated by PAML. SNP was called for each individual using GATK, and genetic diversity was calculated by VCFtools. Linkage disequilibrium was constructed by PopDpDecay. Recombination rate was estimated by FastEPRR. Gene flow between the two populations, effective population size, and divergence time were calculated by fastsimcoal. SV was called by Delly, Lumpy, and Manta. CNV was called by Freec. Methylation data were extracted by Biomark, and DMRs were calculated by R package of DSS. GO enrichment was performed by Metascape. Detailed information is available in SI Appendix, Materials and Methods.

Data Availability
Genome and sequence read archive data have been deposited in National Center for Biotechnology Information (BioProject: PRJNA387778). All the data downloaded from NCBI are listed in SI Appendix. All related data are included in the article and supporting information.

ACKNOWLEDGMENTS
This project was supported by the National Science Foundation of China (32071487), National Key Research and Development Programs (2021YFD1200900), Science Fund for Creative Research Groups of Gansu Province (21J7RA533), Lanzhou University’s “Double First-Class” Guided Project-Team Building Funding-Research Startup Fee for Kexin Li, Chang Jiang Scholars Program, the Fundamental Research Funds for Excellent Youth from the Central Universities, L2U (lzujby-2021-ey17, lzujby-2020ct02), a grant from State Key Laboratory of Grassland Agro-Ecosystems (Lanzhou University) (Grant Numbers: SKLAE.202001, 202009, and 202010). We are also grateful to the Ancell-Teicher Research Foundation for Genetic and Molecular Evolution for its constant financial support for the Spalax research program. We received support for computational work from the Big Data Computing Platform for Western Ecological Environment and Regional Development and Supercomputing Center of Lanzhou University.
