In Pre-Big-Bang and in Ekpyrotic Cosmology, perturbations on cosmological scales today are generated from quantum vacuum fluctuations during a phase when the Universe is contracting (viewed in the Einstein frame). The backgrounds studied to date do not yield a scale invariant spectrum of adiabatic fluctuations. Here, we present a new contracting background model (neither of Pre-Big-Bang nor of the Ekpyrotic form) involving a single scalar field coupled to gravity in which a scale-invariant spectrum of curvature fluctuations and gravitational waves results. The equation of state of this scalar field corresponds to cold matter. We demonstrate that if this contracting phase can be matched via a nonsingular bounce to an expanding Friedmann cosmology, the scale-invariance of the curvature fluctuations is maintained. We also find new background solutions for Pre-Big-Bang and for Ekpyrotic cosmology, which involve two scalar fields with exponential potentials with background values which are evolving in time. We comment on the difficulty of obtaining a scale-invariant spectrum of adiabatic fluctuations with background solutions which have been studied in the past.

I. INTRODUCTION

Both Pre-Big-Bang and Ekpyroic cosmology are attempts to construct alternatives to inflationary cosmology by introducing ideas of string theory to cosmology. The Pre-Big-Bang scenario \cite{1} is based on considering the dilaton at an equal footing to the gravitational field, motivated by the fact that these are the important low energy degrees of freedom. The action is given (in the string frame) by

$$S = \frac{1}{2\kappa^2} \int d^4x \sqrt{-g} e^{-\varphi} \left( R - (\partial \varphi)^2 \right), \quad (1)$$

where $\varphi$ denotes the dilaton and $\kappa^2 \equiv M_{\text{pl}}^{-2} \equiv 8\pi G$. The Universe is assumed to begin in a cold empty state with an accelerating dilaton. The initial evolution is dominated by the effects of the dilaton, and in the string frame yields super-exponential expansion. In the Einstein frame, this corresponds to a contracting phase with a scale factor $a(t)$ given by $a(t) \sim (-t)^{1/3}$ (the time $t$ is negative in this phase). By a duality transformation, this solution is related to an expanding Friedmann-Robertson-Walker cosmology. Without corrections to the action \cite{1}, however, the initial dilaton-dominated (pre BB) branch and the late time expanding (post BB) branch are separated by a singularity. Since the Hubble radius decreases faster than the physical wavelength corresponding to fixed comoving scales, quantum fluctuations on microscopic scales during the pre BB branch can be stretched to scales which are cosmological at the present time, as in the case of inflationary cosmology. See e.g. \cite{2} for recent reviews of Pre-Big-Bang cosmology.

The Ekpyrotic scenario \cite{4} (see also \cite{5}) assumes that the visible Universe is a boundary brane in five dimensional bulk space-time, and that the heating event which resulted from the collision of this brane with a parallel one which is attracted to it by an inter-brane potential $V(\varphi)$. The dynamics is described by a four-dimensional toy model in which the separation of the branes in the extra dimension is modeled as a scalar field $\varphi$. The effective action is taken to be

$$S = \int d^4x \sqrt{-g} \left( \frac{1}{2\kappa^2} R + \frac{1}{2} (\partial \varphi)^2 - V(\varphi) \right), \quad (2)$$

with a potential which for values of $\varphi$ relevant to the generation of cosmological fluctuations is given by

$$V(\varphi) = -V_0 e^{-\sqrt{2}(m_p)^{-1}\varphi}, \quad (3)$$

where $0 < p \ll 1$ and $m_p$ denotes the 4-d Planck mass (using the notation of \cite{1}). The branes are assumed to start out widely separated and at rest. In this case, the energy is negative and the scale factor associated with the action \cite{2} is contracting with $a(t) \sim (-t)^p$ (the time $t$ is again negative in this phase). The time $t = 0$ corresponds to a singularity of the four dimensional model \cite{4}, as in the case of Pre-Big-Bang cosmology \cite{1}. As in

*See, however, \cite{6,7,8,9,10} for criticism of the scenario.
the case of Pre-Big-Bang cosmology, comoving scales contract less fast than the Hubble radius during this phase, and thus it is again possible that microscopic sub-Hubble scale fluctuations during the phase of contraction produce perturbations on cosmological scales today.

Neither for Pre-Big-Bang cosmology nor in the Ekpyrotic scenario is a scale-invariant spectrum of adiabatic fluctuations generated at the level of the single field actions described above. A heuristic way to understand this is to note that the initial values of the fluctuations when they exit the Hubble radius are set by the Hubble constant. The Hubble constant is increasing rapidly as a function of time in both scenarios, and thus a deeply blue spectrum of initial fluctuations will result (spectral index \( n = 4 \) in the case of Pre-Big-Bang cosmology, \( n = 3 \) in the case of the Ekpyrotic scenario). Careful studies taking into account the gravitational dynamics on super-Hubble scales confirmed this result both for Pre-Big-Bang cosmology at a nonsingular bounce, and in the Ekpyrotic scenario [12]. Such a model is obtained here by considering an exponential potential for the scalar field. In the PBB scenario, exponential potentials for the dilaton may be generated by non-perturbative effects or by considering non-critical string theory (a cosmological constant in the string frame can generate an exponential potential in the Einstein frame).

In order to connect the contracting phase to an expanding phase, it is necessary to assume that at sufficiently high curvatures corrections to Einstein gravity become important, yielding a nonsingular bounce. Similar ideas are invoked to achieve a graceful exit in Pre-Big-Bang cosmology. In Section 3 we apply matching conditions [20,21] corresponding to continuity of the induced metric and of the extrinsic curvature for the infrared modes to calculate the induced curvature fluctuations in the expanding phase. We find that the dominant mode of the curvature perturbation \( \zeta \) in the expanding phase inherits the scale-invariance of the growing mode of the contracting phase. A new aspect of this matching problem is that the dominant mode of \( \zeta \) increases on super-Hubble scales in the contracting phase, in contrast to what occurs in inflationary cosmology, where it is constant.

In Section 4 we study backgrounds with two scalar matter fields. Note that both for Pre-Big-Bang cosmology and in the Ekpyrotic scenario, there are other light fields which should be included in the respective actions [10] and [8]. In both cases there are axion and moduli fields which could play an important role. These fields can be dynamical during the collapse phase [22].

In the case of Pre-Big-Bang cosmology, it was realized [23] that, in the presence of moving extra dimensions, axion fluctuations are amplified, and that the motion of the extra dimensions can be chosen such that a scale-invariant spectrum of isocurvature perturbations results (for more work along these lines see e.g. [24,25]). However, such a primordial spectrum of inhomogeneities seeded by axion fluctuations is ruled out by the latest CMB anisotropy results (see e.g. [26] for an analysis of this issue).

In Section 4 of this paper, we present a new class of two scalar field backgrounds. These backgrounds have an interpretation both in the case of the Pre-Big-Bang scenario and in Ekpyrotic cosmology. In the former case they correspond to a dilaton-axion background with exponential dilaton potential, in the latter case they involve the scalar field \( \varphi \) representing the separation of the two branes and a rolling axion.

II. FLUCTUATIONS IN SINGLE FIELD BACKGROUND MODELS

We begin with a brief review of the analysis of the spectrum of cosmological fluctuations in single field background models.

To linear order in fluctuations (and neglecting gravitational waves and vector modes), the metric can be written as (see e.g. [27] for a comprehensive review)

\[
d s^2 = a^2(\eta) \left[ (1 + 2\Phi) d\eta^2 - (1 - 2\Phi) dx^i dx^i \right],
\]

where \( \eta \) is conformal time. We have used the fact that if matter consists of scalar fields there is to linear order no anisotropic stress.

Via the Einstein constraint equations, the linear gravitational fluctuations (described by \( \Phi \)) are coupled to the matter field fluctuations. In the single matter field case, with matter fluctuations denoted by \( \delta \varphi \), a convenient and gauge-invariant variable is [27] (see also [28]).
\[ v = a (\ddot{\varphi} + \frac{\Phi}{H} \dot{\Phi}) \equiv a Q , \]  

(5)

with an overdot denoting the derivative with respect to physical time \( t \). In particular, in the action for joint metric and matter fluctuations, \( v \) is a canonically normalized field, and hence it is useful to quantize the fluctuations in terms of it. We will be studying the linear perturbation equations for this variable in momentum space, with \( k \) standing for comoving momentum.

In an expanding Universe described by the Einstein equations, a convenient variable to use to track the amplitude of the fluctuations on super-Hubble scales is \( \zeta \), the curvature perturbation in comoving gauge.\(^{29,30} \) In variable \( \zeta \) is related to the metric fluctuations via

\[ \zeta = \frac{2 \Phi + H^{-1} \dot{\Phi}}{3 (1 + w)} + \Phi . \]  

(6)

and it is related to \( Q \) and \( v \) as follows:

\[ \zeta = \frac{H}{\phi} Q = \frac{v}{z} , \]  

(7)

with

\[ z = \frac{a \dot{\varphi}}{H} . \]  

(8)

In an expanding Universe and in the absence of entropy fluctuations, \( \zeta \) is constant on scales larger than the Hubble radius, as can be seen from its equation of motion which is

\[ \dot{\zeta} = - \frac{H k^2}{a^3} \Phi . \]  

(9)

In inflationary cosmology, it is thus useful to calculate the magnitude of \( \zeta \) at the time when the fluctuation scale becomes larger than the Hubble radius, to use the constancy of \( \zeta \) to evolve until the time when the scale re-enters the Hubble radius, and to infer the values of \( \Phi \) and \( \dot{\Phi} \) (which determine, for example, the spectrum of CMB anisotropies) at that time.

However, in the case of a contracting Universe one must (even in the absence of entropy fluctuations) be more careful, since the term in \( \Box \) proportional to \( k^2 \) may grow. In the case of Pre-Big-Bang cosmology, the growth is only logarithmic in \( \eta \), and for the potential used in the original version of the Ekpyrotic model there is no growth of \( \zeta \) at all. Hence, in these models \( \zeta \) remains a good variable to follow the magnitude of the density fluctuations on super-Hubble scales.

In the Einstein frame, the equations of motion for cosmological perturbations reduce to the following equation for the Fourier mode of the variable \( v \) defined in \( \Box \) with comoving wavenumber \( k \) (we suppress the index \( k \) on \( v \))

\[ v'' + \left( k^2 - \frac{z''}{z} \right) v = 0 , \]  

(10)

where a prime denotes the derivative with respect to conformal time \( \eta \).

Making use of the background equations of motion, this equation becomes

\[ v'' + \left( k^2 - \frac{a''}{a} + a^2 V'' \right) \]  

(11)

\[ + 2 a^2 \left[ \frac{H}{H} + 3 H \right] v = 0 , \]

where \( V \) is the potential of the matter field \( \varphi \). From this equation is is clear that on scales much smaller than the Hubble radius, \( v \) is oscillating with frequency given by \( k \). The vacuum state normalization of \( v \) on these scales is

\[ v = \frac{1}{\sqrt{2k}} e^{-i k \eta} . \]  

(12)

We consider backgrounds which correspond in the Einstein frame to power law contraction

\[ a(t) \propto (-t)^p . \]  

(13)

In this case, the last two terms within the parentheses multiplying \( v \) in \( \Box \) cancel, and the equation reduces to

\[ v'' + \left( k^2 - \frac{p(2p-1)}{(p-1)^2} \right) v = 0 . \]  

(14)

Its solution can be expressed in terms of Bessel functions \( Z_\nu \):

\[ v = \sqrt{-\eta} Z_\nu(-k \eta) \]  

(15)

where the index \( \nu \) is related to the index \( p \) by

\[ \frac{\nu^2 - 1}{4} = \frac{p(2p-1)}{(p-1)^2} \]  

(16)

and therefore

\[ \nu = \frac{1}{2} \left( 1 - \frac{3}{p} \right) . \]  

(17)

As can be seen from the large argument expansion of the Bessel functions, this solution automatically has the correct vacuum normalization.

Making use of the long wavelength limit of the Bessel functions, and of the fact that for our class of backgrounds \( \dot{\varphi}/H \) is independent of time, we obtain the following power spectrum of the variable \( \zeta \):

\[ P_\zeta(k) = \frac{k^3}{2\pi^2} |\zeta|^2 \sim p k^{3-2\nu} . \]  

(18)

Thus, to obtain a scale-invariant spectrum of adiabatic fluctuations, we require \( \nu = 3/2 \), whereas in the single field Ekpyrotic scenario with \( p \sim 0 \) one obtains \( \nu \sim 1/2 \) and thus spectral index \( n \sim 3 \). In the single field Pre-Big-Bang scenario the resulting values are \( p = 1/3 \), \( \nu = 0 \) and therefore \( n = 4 \).
An interesting background is obtained if \( p = 2/3 \). In this case, \( \nu = 3/2 \) and hence a scale-invariant spectrum of adiabatic curvature fluctuations is generated in the collapsing phase. This background corresponds to a contracting Universe dominated by cold matter with equation of state \( P = 0 \) (with \( P \) denoting pressure). The cold matter in this case is modeled by a scalar field with an exponential potential. Note that the fluctuations in this model behave differently than the fluctuations in a hydrodynamical model with \( P = c_s^2 = 0 \), where \( c_s^2 \) is the speed of sound. This can be seen by comparing the equation of motion \( (11) \) for scalar-field-induced fluctuations with the corresponding equation for hydrodynamical matter (see Chapter 5 of \([26]\)). Note that modeling cold matter by a scalar field with nontrivial potential will avoid the Jeans instability problem on small scales which plagued \( P = 0 \) hydrodynamical matter. Note also that such a contraction \( (a(t) \sim (-t)^{2/3}) \) solve the horizon problem.

### III. Spectrum of Fluctuations After the Bounce

Let us consider the contracting model with \( p = 2/3 \) introduced above and imagine that it is connected via a nonsingular bounce to an expanding Friedmann-Robertson-Walker cosmology. In the following we will argue that in such a model the scale-invariant spectrum of \( \zeta \) connects through the bounce to a late time scale-invariant spectrum in the expanding phase. Thus, our model yields an alternative to cosmological inflation in providing a mechanism for producing a scale-invariant spectrum of adiabatic fluctuations on scales which could, provided that the phase of contraction lasts sufficiently long, be of cosmological interest today.

The graceful exit problem faced in order to obtain such a bounce is similar to what is required to obtain a graceful exit in Pre-Big-Bang cosmology. In the latter case, there are indications that higher curvature and string loop effects can yield a nonsingular bounce \([32,33,34,35,36]\) (see also \([37,38]\)). Back-reaction effects also can play an important role \([39]\). There is also a construction \([10,11]\) based on a Lagrangian with higher order corrections of the nonsingular Universe construction \([12,13]\) which yields such a regular bounce. Since the corrections to Einstein gravity will be important only very close to the bounce, and since we are interested in scales which at the bounce are much larger than the Hubble radius, it appears reasonable to model the bounce (for the purpose of matching the pre-bounce and post-bounce fluctuations) as a gluing of two Einstein Universes at a fixed surface specified by some physical criterion (see, however, the concerns raised in \([15,16]\) on this issue).

The naive expectation is that the dominant mode of the curvature fluctuation \( \zeta \) after the bounce (which is constant in time) is given by the dominant mode prior to the bounce, the mode which in our background has a scale-invariant spectrum. This is what happens in inflationary cosmology with reheating modeled as a discontinuous change in the equation of state \([44,45]\). Pre-Big-Bang cosmology \([21]\) and in the Ekpyrotic scenario with a nonsingular bounce \([3]\). Note however, that a similar “plausibility” argument applied to the variable \( \Phi \) fails in both of the above cases. In both Pre-Big-Bang and Ekpyrotic cosmology the pre-bounce growing mode of \( \Phi \) does not contribute to leading order in the wavenumber \( k \) to the dominant post-bounce mode of \( \Phi \). Thus, in order to be able to draw conclusions about the post-bounce spectrum, it is necessary to carefully match the fluctuation variables at the bounce.

The general relativistic matching conditions demand that at the boundary surface the induced surface metric and the extrinsic curvature be continuous \([22,23]\). As matching surface one can choose either a constant energy density surface (from the point of view of longitudinal gauge) or a constant scalar field surface \([4]\). For super-Hubble scale fluctuations, the difference between these two surfaces is of order \( k^2 \) and does not affect the results to leading order in \( k^2 \). The matching on a constant energy density surface implies the continuity of \( \zeta \) and \( \Phi \) across the surface. In Pre-Big-Bang cosmology \([21]\) and in the Ekpyrotic scenario \([13]\) this leads to the conclusion that the growing mode of \( \Phi \) during the collapse phase (which in the case of the Ekpyrotic scenario has a scale-invariant spectrum) does not couple to leading order in \( k^2 \) to the dominant (constant) mode of the post-bounce phase. In contrast, the late time value of \( \zeta \) is the same as at the bounce. These results are confirmed in studies of cosmological perturbations in generalized Einstein theories \([16,46,47]\) which yield a bounce (see also \([15,16]\)).

At the end of Section II we have shown that, for our new background, the growing mode of \( \zeta \) in the contracting phase obtains a scale-invariant spectrum. We need to show that to leading order in \( k^2 \) there is a non-vanishing coupling between the pre-bounce growing mode of \( \zeta \) and the post-bounce dominant mode. Note that the rapid growth of \( \zeta \) is very different from what occurs in the inflationary Universe, in Pre-Big-Bang cosmology and in the Ekpyrotic scenario, and that the analysis of the matching conditions needs to be reconsidered.

We begin with the following general solution (to leading order in \( k^2 \)) for \( \zeta \) (see e.g. Eq. (12.27) in \([2]\)):

\[ \zeta(t) = \text{constant} \]

\[ \Phi(t) = \text{constant} \]

**This result was already noted in the work of \([31]\), and more recently in \([13]\) (it can be also seen from Fig. 3 of \([16]\)). In the earlier work \([31]\), however, the transition to an expanding phase was not discussed.**
\[ \zeta = D + S \int \frac{d\eta}{\varphi^2}, \]  
(19)

where \( D \) and \( S \) are constant coefficients. In our background, the \( S \) mode is the growing one, whereas in inflationary cosmology it is decaying and thus subdominant. Making use of (14), we can find the corresponding form of \( \Phi \):

\[ \Phi = -\frac{1}{2m_p^2 a^2} \mathcal{H} \left( \frac{S}{k^2} \right), \]  
(20)

where \( \mathcal{H} \) is the Hubble constant in conformal time. This gives the mode of \( \Phi \) which is decaying in inflationary cosmology. It also shows that this “decaying” mode of \( \Phi \) affects the value of \( \zeta \) to order \( k^2 \) (to leading order it cancels out). There is also a constant mode of \( \Phi \) which determines the constant mode (D mode) of \( \zeta \). The coefficients of the constant modes of \( \Phi \) and \( \zeta \) are related by a function of the equation of state of the background which contains no k-dependence. Thus, in order to perform the matching analysis we consider the following forms for \( \Phi \) and \( \zeta \):

\[ \zeta = D + S f(\eta), \]  
\[ \Phi = \alpha D + \beta \frac{S}{k^2} \mathcal{H}, \]  
(21)

where \( f(\eta) = \int \frac{d\eta}{\varphi^2} \) and where the coefficients \( \alpha \) and \( \beta \) depend only on the equation of state.

It is now straightforward to calculate the consequences of the continuous matching of \( \Phi \) and \( \zeta \) across the bounce for the coefficients of the two modes of \( \zeta \) before and after the bounce. Quantities before the bounce will be denoted by a superscript \(-\), those after the bounce by a superscript \(+\). Simple algebra yields

\[ D^+ \left(1 - \frac{\alpha^+ f^+ a^2 k^2}{\beta^+ \mathcal{H}^+} \right) = D^- \left(1 - \frac{\alpha^- f^- a^2 k^2}{\beta^- \mathcal{H}^-} \right) \]
\[ + S^- \left( f^- - \frac{\beta^- \mathcal{H}^-}{\beta^+ \mathcal{H}^+} f^+ \right). \]  
(22)

In the Ekpyrotic scenario, it follows from (13) and from the fact that \( \nu = 1/2 \) that \( D^- \sim k^{-1/2} \) and \( S^- \sim k^{1/2} \). Hence, the D-mode of \( \zeta \) after the bounce has spectral index \( n = 3 \), in agreement with our earlier matching results (13). However, for our present background we have \( \nu = 3/2 \) and hence \( D^- \sim k^{3/2} \) and \( S^- \sim k^{-3/2} \). Since the matching of the \( S^- \) mode to the \( D^+ \) mode is not suppressed by factors of \( k^2 \), the post-bounce \( D^+ \) mode inherits the scale-invariance of the pre-bounce \( S^- \) mode. Thus, we have shown that our background yields a scale-invariant spectrum of fluctuations at late times.

Let us now return to the analysis of Section II and determine the amplitude of the scale-invariant spectrum of curvature perturbations at (and, as we have shown above, therefore also after) the bounce in our model with \( p = 2/3 \). As follows from Eq. (13) and from the background values of \( \varphi \) and \( H \):

\[ \zeta = \frac{H}{\varphi} Q = \sqrt{\frac{p}{2} \frac{Q}{M_{\text{pl}}} \frac{Q}{k^2}}, \]  
(23)

According to (13), the normalized solution for \( Q \) is:

\[ Q = e^{i(\varphi + 1/2) \eta} \frac{\sqrt{-2\pi \eta}}{2a} H_\nu(-k \eta) \]  
(24)

where \( H \) denotes the Hankel function, \( \tilde{\nu} = |\nu| \), and where the scale factor is expressed in terms of conformal time as

\[ a(\eta) = (-1 - p) M_{\text{pl}} \eta \]  
(25)

By inserting the long-wavelength limit \((-k \eta \ll 1\) of the Hankel function one gets:

\[ P_\zeta(k) = \frac{k^3}{2\pi^2} \left| \zeta \right|^2 = p 2^{p-3} \frac{\Gamma(\tilde{\nu})^2}{2^{\tilde{\nu} - 1} M_{\text{pl}}^p} \frac{4\tilde{\nu} M_{\text{pl}}^{2\tilde{\nu}-3}}{k^{2\tilde{\nu}-3}}. \]  
(26)

For \( p = 2/3 \) one has an amplitude in agreement with observations for \( H_s/M_{\text{pl}} \sim 10^{-1} \), where \( H_s \) indicates the absolute value of the Hubble rate at the bounce (when the contraction stops).

The model with \( p = 2/3 \) which we are considering also generates a scale-invariant spectrum of gravitational waves, as already realized in [50] and [31]. This can be seen immediately since \( h = ah \), where \( h \) is the amplitude of the tensor perturbation of the metric, obeys the same equation of motion as the scalar fluctuation variable \( v \). This is true in all models with an exponential potential for the scalar field [32]. In order to compare the amplitudes of the power spectra \( P_\zeta \) for scalar metric fluctuations and \( P_h \) for gravitational waves in the collapsing phase, we first need to divide \( v \) by \( M_{\text{pl}} \) (for dimensional reasons). Then, using the relation between \( \zeta \) and \( v \) and the background values of \( H \) and \( \varphi \) we immediately obtain

\[ \frac{P_\zeta}{P_h} = \frac{p}{2}. \]  
(27)

This is a definite prediction resulting from the analysis during the contracting phase.

IV. A BACKGROUND WITH TWO EVOLVING FIELDS

We now turn to the question of whether it might be possible to generate a scale-invariant spectrum of adiabatic fluctuations in Pre-Big-Bang cosmology and in the Ekpyrotic scenario by turning on nontrivial background time-dependence of a suitably chosen second scalar field. As a first step, we will have to construct new background solutions. We will consider the action

\[ \mathcal{L} = \mathcal{L}_0 + \mathcal{L}_1 + \mathcal{L}_2 + \mathcal{L}_3, \]  
(28)

where \( \mathcal{L}_0 \) is the standard scalar field Lagrangian with potential \( V(\varphi) \), \( \mathcal{L}_1 \) describes the coupling of the scalar field to gravity, \( \mathcal{L}_2 \) includes higher-derivative terms, and \( \mathcal{L}_3 \) is the action for the second scalar field. The goal is to find solutions for \( \varphi \) and \( \phi \) that reduce the effective potential to a scale-invariant form. This requires solving a set of coupled differential equations for the fields and their derivatives. The problem becomes more complex when the second field is introduced, as it adds an additional degree of freedom to the system. However, by carefully choosing the form of \( \mathcal{L}_3 \), it is possible to derive solutions that exhibit scale-invariant properties. This approach allows for a richer cosmological landscape and provides insights into the possible mechanisms for generating the observed spectrum of fluctuations.
\[ S = \int d^4x \sqrt{-g} \left( \frac{1}{2\kappa^2} R + \frac{e^{\alpha \sigma/M_{pl}}}{2} (\partial \sigma)^2 + \frac{1}{2}(\partial \varphi)^2 - V(\varphi) \right), \]  

with an exponential potential for \( \varphi \):
\[ V(\varphi) = -V_0 e^{-\beta \varphi/M_{pl}}. \]  

In the Ekpyrotic scenario, the interpretation of this action is that we add to the single field action \( \mathcal{H} \) (with \( \varphi \) representing the separation of the branes) an axion field \( \sigma \) with non-minimal coupling to gravity. In Pre-Big-Bang cosmology, the interpretation of \( \mathcal{H} \) is to add an exponential potential for the dilaton \( \varphi \) and an axion-like field (non-minimally coupled in the Einstein frame) to the original action of \( \mathcal{H} \). For \( \alpha = 0 \) the field \( \sigma \) should be interpreted as a modulus field.

We now look for self-consistent analytical solutions of the background equations:
\[ \mathcal{H}'^2 = \frac{1}{3M_{pl}^2} \left( \frac{\varphi'^2}{2} + a^2 V(\varphi) + e^{\alpha \sigma/M_{pl}} \sigma'^2 \right), \]  
\[ \varphi'' + 2\mathcal{H}\varphi' + a^2 \mathcal{V} = \frac{\alpha}{2M_{pl}} e^{\alpha \sigma/M_{pl}} \sigma'^2 \]  
\[ \sigma'' + (2\mathcal{H} + \alpha \frac{\varphi'}{M_{pl}}) \sigma' = 0. \]

We consider the following ansatz for \( a(\eta) \) and \( \varphi(\eta) \):
\[ a(\eta) = (-M_{pl}(1-p)\eta)^{-\frac{\beta}{1-p}} \]  
\[ \varphi(\eta) = A \log(-M_{pl}(1-p)\eta) \]  

Eq. (32) can be immediately integrated giving:
\[ \sigma' = C e^{-\alpha \sigma/M_{pl}} \frac{a^2}{a^2} \]  

where \( C \) is an integration constant. We have the following parameters: \( \alpha, \beta, p, A, C \). By imposing that all the terms in the equation for \( \varphi \) have the same time dependence we obtain (assuming \( V_0 \) and \( C \) are nonzero):
\[ \beta \frac{A}{M_{pl}} - \frac{2p}{1-p} = 2 \]  
\[ \alpha \frac{A}{M_{pl}} + \frac{4p}{1-p} = 2 \]

and these relations lead to the constraint
\[ \alpha/\beta = 1 - 3p. \]  

Note that this relation implies that for the case of Pre-Big-Bang cosmology with \( p = 1/3 \) our action describes a modulus field \( \sigma \) minimally coupled in the Einstein frame, whereas in the case of the Ekpyrotic scenario, \( \sigma \) corresponds to an axion.

From the equation for \( \mathcal{H}' \):
\[ \mathcal{H}'^2 - \mathcal{H}^2 = -\frac{1}{2M_{pl}^2} \left[ \varphi'^2 + \sigma'^2 e^{\alpha \sigma/M_{pl}} \right] \]  

we get:
\[ \left( \frac{A}{M_{pl}} \right)^2 + \left( \frac{C}{M_{pl}^2 (1-p)} \right)^2 = \frac{2p}{(1-p)^2}. \]

The interpretation of this result is that \( A/M_{pl} \) and \( C/[M_{pl}^2 (1-p)] \) are constrained to be on a circle of radius proportional to \( \sqrt{p} \). From the energy constraint (30) we obtain:
\[ -\frac{V_0}{M_{pl}^4} = p(3p - 1). \]

This concludes all of the independent relations between the parameters and integration constants for the exact solution for the background obtained from the ansatz (31).

Let us compare the dependence of \( a \) and \( V(\varphi) \) on \( p \) and on time in our two field solution with the corresponding scalings in the single field model of Section II. Comparing (33) with (25) it follows that the dependence of \( a \) on \( p \) and on time is the same. Inserting (34) into (29), making use of (41), and comparing with the result in the single field case (see e.g. Eq. (12) of [13]) it follows that the dependence of \( V(\varphi) \) on \( p \) and on time is also identical. This implies that the dependence on \( p \) of the spectrum and amplitude of gravitational waves is the same in the single field and multi field models. Eq. (31) shows that the sum of the kinetic terms in the multi field model with the axion is the same of the single field model.

A final remark for the case \( \alpha = 0 \), in which \( \sigma \) corresponds to a modulus field. The solution obeying the ansatz (34) constructed in this section has a meaning for \( \alpha = 0 \), only in the case \( p = 1/3 \), i.e. vanishing potential for \( \varphi \). Only in this case analytic solutions exist, since both \( \varphi \) and \( \sigma \) are massless, and the global equation of state is stiff matter (pressure density equal to energy density). In the case of an exponential potential as in Eq. (24), the modulus \( \sigma \) dominates the energy density for early times if \( p < 1/3 \) and for late times if \( p > 1/3 \).

**V. DISCUSSION**

In this paper we have discussed ways of obtaining a scale-invariant spectrum of adiabatic fluctuations in

\[ \ldots \]
models in which a contracting Universe is matched via a nonsingular bounce to an expanding Friedmann-Robertson-Walker cosmology. We have assumed that new physics at high curvatures leads to a short period in which the background evolution is not described by the Einstein equations, thus enabling a transition from a contracting to an expanding phase (from the point of view of the Einstein frame scale factor).

Our first result is that a contracting Universe dominated by cold matter modeled as a scalar field with an exponential potential with appropriately chosen index can yield a scale-invariant spectrum of curvature fluctuations (fluctuations in the variable $\zeta$) in the contracting phase, which is matched at the bounce to a scale-invariant spectrum during the expanding phase.

Our second result is that it is possible in the context of Ekpyrotic cosmology (and also of other models with a phase of power law contraction with power $p \neq 1/3$) to obtain new background solutions by considering a model with two scalar fields $\varphi$ and $\sigma$, with exponential potential for $\varphi$ and non-minimal coupling for $\sigma$, provided that the coefficients in the exponents of the potential and describing the non-minimal coupling satisfy a particular relation. In the context of Ekpyrotic cosmology, this corresponds to adding to the usual four-dimensional effective action which contains a scalar field $\varphi$ describing the separation of the branes an axionic field $\sigma$. It is important that both fields have time-dependent backgrounds. In the context of the Pre-Big-Bang scenario, our model can be interpreted as adding to the dilaton-gravity action an axion field, and assuming that there is an exponential potential for the dilaton.

Adding the new degree of freedom via the second scalar field leads to an isocurvature mode of the fluctuations. In the PBB scenario, it was shown that for suitable field backgrounds this isocurvature mode has a scale invariant spectrum. However, because of the absence of a potential, the isocurvature and adiabatic modes are not coupled and a spectrum seeded by isocurvature axion fluctuations seems in conflict with observations. In our backgrounds, adiabatic and isocurvature fluctuations are coupled and it might be possible to induce directly a scale invariant spectrum of adiabatic fluctuations.

This mechanism is an alternative to the one proposed recently based on axion decay to obtain a scale-invariant spectrum of adiabatic curvature fluctuations. One starts with a scale-invariant spectrum of isocurvature fluctuations (like in the work of [23]), and assumes that the axion field which is responsible for the scale-invariant spectrum decays at some late time when it dominates the background energy density.

Acknowledgments

We wish to thank D. Wands for useful correspondence. This research was supported in part by the U.S. Department of Energy under Contract DE-FG02-91ER40688, TASK A (R.B., Brown Univ.). Both authors thank the TH Division at CERN for hospitality during the course of this work.
