We present a systematic study of the magnetization in YbRh$_2$Si$_2$ under slightly negative (6% Ir substitution) and positive (7% Co substitution) chemical pressure. We show how the critical field $H_N$, associated with the high-field Lifshitz transitions, is shifted to lower (higher) values with Co (Ir) substitution. The critical field $H_N$ which identifies the boundary line of the antiferromagnetic (AFM) phase $T_N(H)$ increases with positive pressure and it approaches zero with 6% Ir substitution. On the other side, the crossover field $H^*$ associated with the energy scale $T^*(H)$ where a reconstruction of the Fermi surface has been observed, is not much influenced by the chemical substitution. Following the analysis proposed in Refs. [1–4] we have fitted the quantity $M(H) = M + (dM/dH)H$ with a crossover function to indentify $H^*$. The $T^*(H)$ line follows an almost linear $H$-dependence at sufficiently high fields outside the AFM phase, but it deviates from linearity at $T \leq T_N(0)$ and in Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ it changes slope clearly inside the AFM phase. Moreover, the full width at half maximum (FWHM) of the fit function depends linearly on temperature outside the phase, but remains constant inside, suggesting either that such an analysis is valid only for $T \geq T_N(0)$ or that the Fermi surface changes continuously at $T = 0$ inside the AFM phase.

1 Introduction The general understanding of quantum critical points (QCPs) is based on the concept of a single energy scale that fades continuously for $T \rightarrow 0$. The conventional theoretical approach associates with this energy scale an order parameter that is defined finite inside a region of the phase diagram and zero elsewhere [5–7]. The corresponding phase transition at $T = 0$ is a quantum phase transition (QPT). If this region is separated from the rest by a second-order phase transition line, a QCP exists at the QPT. In materials with magnetic phase transitions, the energy scale is usually considered to be the ordering transition temperature – e.g., in the case of antiferromagnetic (AFM) systems, this is the Néel temperature $T_N$ – and the order parameter is the staggered magnetization [8, 9]. In metallic systems the magnetic order can be of the spin-density-wave (SDW) type and the same electrons which form the Fermi surface are involved in the QPT. Prominent examples of quantum critical systems are heavy-fermion compounds because of the small energy scale associated with the hybridization between nearly localized $f$-electrons with the conduction electrons. Here, the QPT separates a paramagnetic (PM) heavy Fermi liquid (FL) from an AFM metal. In these systems there are two principal energy scales: $k_BT_K$ and $k_BT_{RKKY}$ which derive from the respective interactions, the Kondo and the RKKY. $T_K$ defines the temperature at which the localized $f$-electrons start to hybridize with the itinerant $d$-electrons to form a larger and heavier Fermi surface, $T_{RKKY}$ is a measure of the inter-site exchange magnetic coupling. The interplay between these energy scales determines the magnetic ordering temperature $T_N$ and characterizes the QCP [10]. In real systems, however, the situation can be rather more complex, due to the presence of multiple energy scales that can get involved in the QPT [2]. In addition, many materials show more than just a single magnetic phase transition. Therefore, experimental studies of quantum criticality become quite demanding but, on the other hand, promising for the discovery of novel correlated phases of condensed matter.
A prototypical example of such a complex system is the tetragonal YbRh$_2$Si$_2$, which is particularly suitable for studying QPTs [12–14]. In fact, this compound has a large $T_K \approx 25$ K and a very small $T_N = 72$ mK that can be suppressed by a magnetic field $\mu_0 H \approx 60$ mT ($H \perp c$, with $c$ being the magnetically hard axis) or chemical negative pressure ($P \approx -0.25$ GPa) [14–16]. Three other intriguing features have recently been detected: (i) another sharp phase transition at $T = 2.2$ mK [17], (ii) a kink in the magnetization at $H_0 \approx 10$ T [11, 18] and (iii) a crossover energy scale $T^*(H)$ [1, 2]. The origin of the low-$T$ transition is still unclear, but the comparison with the iso-electronic analogue YbCo$_2$Si$_2$ [19, 20] and the evolution of $T_K$ observed in the series Yb(Rh$_{1-x}$Co$_x$)$_2$Si$_2$ (Co substitution corresponds to positive pressure) might suggest a second, possibly first-order, AFM transition [21–23]. The feature at $H_0$ has been interpreted as field-induced suppression of the HF state, as hydrostatic pressure experiments have revealed a clear correspondence between $H_0$ and the Kondo scale $T_K$ [11, 18]. Accurate de-Haas-van-Alphen experiments could show that the Fermi surface smoothly changes at $H_0$ suggesting a Lifshitz-type like of transition [24]. Meanwhile, thermopower experiments and renormalized band structure calculations have undoubtly demonstrated that the anomaly at $H_0$ is caused by the field-induced shift of a van-Hove singularity (in the quasiparticle density of states) through the Fermi level, causing two consecutive Lifshitz transitions [25, 26]. Finally, there is the crossover line $T^*(H)$ which has been found in measurements of the Hall-effect [1] and various other thermodynamic properties [2]. The full width at half maximum (FWHM) of these crossovers displays a linear temperature dependence [3, 27]. This suggests a step-like change of the Hall coefficient at $T = 0$ implying a Fermi surface reconstruction. These findings have corroborated a series of previous theoretical proposals which considered the Fermi surface collapse due to the critical breakdown of the Kondo screening effect at the field-induced AFM QCP, including degrees of freedom other than fluctuations of the order parameter [28–31]. In addition, it has been shown that the linear dependence of the FWHM on temperature is consistent with the energy over temperature scaling of the quantum-critical single-electron fluctuation spectrum [27]. However, experimental evidence that the energy scale $T^*(H)$ does not change much under applied pressure [3, 4], while the other energy scales $T_L(H)$, $T_N(H)$ and $T_0(H)$ are very pressure sensitive [15, 16, 23], has reopened the debate on how to interpret the experimental results. Three possibilities are currently considered: (i) the $T^*(H)$ line represents a Kondo-destruction Lifshitz transition inside the magnetic phase with a change between two Fermi surfaces which have different topology [32–35]; (ii) it represents the effect of a Zeeman-induced Lifshitz transition [36–38] (iii) recent inelastic neutron scattering experiments associate the electron spin resonance signal [39] seen in YbRh$_2$Si$_2$ with a field-induced mesoscopic spin resonance, which evolves in field like the $T^*(H)$ line [40].

In this paper we follow the evolution of the three aforementioned energy scales under the effect of chemical pressure by means of magnetization measurements. Pressure is induced by substituting a small amount of either Co (positive pressure) or Ir (negative pressure) for Rh. The substitution is iso-electronic and small, to avoid the effect of disorder. The single crystals were grown from In flux as described in Ref. [41]. The good quality of the samples as well as the good agreement between chemical and hydrostatic pressure is shown in the Supplementary Information of Ref. [3]. Our crystals of YbRh$_2$Si$_2$, Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ and Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ have a residual resistivity of 0.55, 3 and 7.4 $\mu$S cm, respectively. In the Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ sample two phase transitions have been found at $T_N = 410$ mK and $T_L = 60$ mK, whereas in Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ no phase transition has been seen down to 20 mK. The dc-magnetization $M$ has been measured with a high-resolution Faraday magnetometer, in magnetic fields as high as 12 T and temperatures down to 50 mK [42]. The field was applied along the magnetic easy plane, i.e., perpendicular to the crystallographic c-axis. We show how the critical field $H_0$ is shifted to lower (higher) values with Co (Ir) substitution, as expected [11]. On the other side, the crossover field $H^*$ is not much influenced by the chemical substitution. Performing the analysis proposed in Refs. [1–4] we illustrate that $T^*(H)$ seems to follow a linear $H$ dependence outside the AFM phase, deviating from linearity at temperatures close to $T_N(0)$, and in Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ it changes slope inside the magnetic phase. Moreover, the FWHM of the crossover fit function is linear-in-$T$ outside the AFM phases but constant inside the Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ AFM phase, suggesting that either such an analysis is valid only for $T > T_N(0)$ or the Fermi surface changes continuously at $T = 0$.

2 Results and discussion

The first result is illustrated in Fig. 1, where the field-dependent magnetization curves for

![Figure 1](online colour at: www.pss-b.com) Field-dependent magnetization curves for YbRh$_2$Si$_2$, Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ and Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ samples. The upward arrows (↑) indicate the fields $H_0$ estimated by the inflection point of $\delta M(H)/\delta H$ [11]. Inset: log–log plot of the magnetization at 50 mK of YbRh$_2$Si$_2$ for fields extending from 0.1 to 10 T, indicating that $M \propto H^{0.7}$.
YbRh$_2$Si$_2$, Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ and Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ samples are shown up to 12 T. In YbRh$_2$Si$_2$ the magnetization measured at 50 mK shows two clear kinks at about 0.1 (cf. Fig. 2) and 10 T [11]. In between $M$ is proportional to $H^{0.7}$, as demonstrated in the inset of the same figure, possibly reflecting the continuous evolution with magnetic field of the quasiparticle density of states at the Fermi energy [11, 18] given as a consequence of the suppression of the local Kondo effect [43, 25]. The upward arrows (↑) indicate the fields $H_0$, associated with the high-field Lifshitz transitions [11, 44]. In the Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ sample the kink at $H_0$ is shifted to about 5.6 T while in Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ $H_0$ is shifted to 11 T, in agreement with previous pressure studies [11].

We focus now on the energy scale $T^*(H)$. The field $H^*$, associated with this energy scale, was identified in YbRh$_2$Si$_2$ with the change of slope of the quantity $M(H) = M + (dM/dH)H$, i.e., the kink in $M$ vs. $H$, derived from magnetization isotherms (cf. Fig. 2, right panels) [2, 4, 46]. At 50 mK, the kink in $M(H)$ at about $H^* \approx 50$ mT derives from the kink in $M(H)$ at about 100 mT which remains sharp even at temperatures higher than $T_N \approx 72$ mK (cf. curves in middle panels of Fig. 2 at 70 and 90 mK). Therefore, the kink at $H^*$ cannot be associated with the critical field $H_N$ of the AFM phase, but matches quite well the crossover field extracted from Hall-effect, magnetoresistivity and ac-susceptibility measurements [2, 3, 27]. Moreover, $H^*$ is also visible in Yb(Rh$_{0.94}$Ir$_{0.06}$)$_2$Si$_2$ where $T_N$ is almost zero. We have performed the analysis proposed in Refs. [1, 2] for the three single crystals (see Fig. 2). In analogy with the Hall-effect signatures observed at $T^*(H)$, $M$ vs. $H$ might be fitted with the integral of the following step function:

$$f(H,T) = A_2 - \frac{A_2 - A_1}{1 + (H/H^*)^{\gamma}},$$  \hspace{1cm} (1)

where parameters $A_1$ and $A_2$ denote the linear slope of $M$ vs. $H$ before and after the kink. Since $M$ vs. $H$ is not linear for $H \geq H^*$, we have previously used the quantity $\overline{M} = M + (dM/dH)H$ vs. $H$ which represents the derivative of the magnetic free energy and is almost linear above $\mu_0 H = 0.5$ T up to at least 2 T (right frames of Fig. 2). We have performed these fits for all our isotherms as shown in the right panels of Fig. 2. It is worth mentioning, that, for instance, the fact that at 50 mK in the stoichiometric crystal the critical fields $H_N$ and $H^*$ almost coincide would imply that at temperatures lower that 50 mK these energy scales might intersect each other (this hypothesis is currently being investigated by measurements of the Hall effect under pressure). For Co concentrations higher than 7% this analysis could not be performed anymore because of the high $H_N$ and the stronger curvature of $M$ vs. $H$. In the right frames of Fig. 2 the black lines are the fit to the data performed by integrating Eq. (1). The little humps are a consequence of the weak kinks in the magnetization isotherms due to the transition at $H_N$ from the AFM phase into the PM phase. At these kinks $dM(H)/dH$ decreases slightly and $M(H)$ shows a drop which is small when compared to the main magnetization signal. These humps are not considered during the fit procedures. This can be seen in the right panel of Fig. 2 where $M(H)$ vs. $H$ is plotted for YbRh$_2$Si$_2$: the fit function for the data at 70 mK which show no hump since $T \approx T_N$ lies on the top of the fit function for the data at 50 mK which show a clear hump at $H_N$. The same is valid for Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ where $M(H)$ displays a distinct curvature already at fields $H \lesssim H_N$ (see lower right panel of Fig. 2). We can take a closer look at the analysis for Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$. Fig. 3 shows a plot of the magnetization $M(H)$, susceptibility $dM(H)/dH$ and $M(H)$ at fields $\mu_0 H \leq 0.5$ T and selected temperatures $T = 0.05, 0.3$ and 0.4 K, i.e. at and below $T_N = 0.41$ K. There is almost no difference between the curve at $T_N \approx 0.4$ K and the one at 0.3 K, i.e. below $T_N$, indicating that the phase transition is weak. Only well below $T_N$, i.e. at 0.05 K, a tiny

Red lines indicate measurements at temperatures $T < T_N$. $H_N$ and $H^*$ are the fields associated with $T_N$ and $T^*$ at 50 mK. In YbRh$_2$Si$_2$ the two fields almost coincide. Right: $M = M + (dM/dH)H$ vs. $H$ for the same three single crystals. The little humps, visible just above $H_N$, denote the phase transition and their shape is a consequence of how $\overline{M}$ is calculated.
and selected temperatures $T$ maximum ordered moment cannot be larger than 0.15 $T$ at extrapolation from the data above of the ac-susceptibility at 0.04 K. The red dotted line is a linear (online colour at: www.pss-b.com) Plot of the magnetization study of the energy scales in YbRh$_2$Si$_2$.

Figure 3 (online colour at: www.pss-b.com) Plot of the magnetization $M(H)$, susceptibility $dM/dH(H)$ and $M(H) = M(H) + (dM(H)/dH)H$ for Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ at fields $\mu_0H \leq 0.5$ T and selected temperatures $T = 0.05$, 0.3 and 0.4 K, i.e. below and at $T_N = 0.41$ K. In the middle panel we have included a measurement of the ac-susceptibility at 0.04 K. The red dotted line is a linear extrapolation from the data above $H_N$ to $H = 0$ showing that the maximum ordered moment cannot be larger than 0.15 $\mu_B$/Yb.

kink can be seen at 0.22 T. We need to plot the derivative $dM/dH$ vs. $H$ to identify slight drops at the respective critical fields (indicated by arrows). The extrapolated maximum ordered moment (red dotted line in Fig. 3) is 0.15 $\mu_B$/Yb, i.e. very small when compared to the expected crystalline electrical field moment for the Kramers doublet ground state, indicating the presence of a strong Kondo effect. Measurements of the specific heat at zero field provide a value for the entropy below the transition at $T_N$ which is about 1% of Rhn2. Moreover, from the field-dependent nuclear contribution to the specific heat an estimation of the ordered moment can be given and it is below 0.15 $\mu_B$/Yb [44]. This means that the main part of the magnetization signal in field is dominated by the suppression of the screening of the moments rather than by the polarization of the ordered moments even inside the AFM phase. This allows us to fit the data outside and inside the AFM phase by neglecting the few points around $H_N$ during the fit procedure. This is again shown in the bottom panel of Fig. 3 where all the curves change slope at fields close to $H^*$. Even considering the few points below $T_N$ (black dotted line in Fig. 3) would not shift the position of $T^*$ outside the error bars given in Fig. 4 or the FWHM: The fact that $M(H)$ vs. $H$ does not change much when the temperature is lowered below $T_N$ is reflected in the almost constant position of the $T^*(H)$ line inside the AFM phase (grey points in Fig. 4), as observed before [3].

The results of such fits are summarized in the phase diagrams of Fig. 4: the crossover field $H^*$, associated with the energy scale $T^*(H)$, is not much influenced by the chemical substitution when compared to the substantial change of the AFM ordered phase, i.e. the enhancement of $T_N$ and $H_N$. $T^*(H)$ seems to follow a linear $H$ dependence outside the AFM phase, it deviates from linearity at $T < T_N(0)$ and in the Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ sample it changes slope clearly inside the magnetic phase. Correspondingly, the FWHM of the crossover fit function depends linearly on temperature at sufficiently high magnetic fields outside the AFM phase in

![Figure 3](https://example.com/figure3.png)

**Figure 3** (online colour at: www.pss-b.com) Plot of the magnetization $M(H)$, susceptibility $dM/dH(H)$ and $M(H) = M(H) + (dM(H)/dH)H$ for Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$ at fields $\mu_0H \leq 0.5$ T and selected temperatures $T = 0.05$, 0.3 and 0.4 K, i.e. below and at $T_N = 0.41$ K. In the middle panel we have included a measurement of the ac-susceptibility at 0.04 K. The red dotted line is a linear extrapolation from the data above $H_N$ to $H = 0$ showing that the maximum ordered moment cannot be larger than 0.15 $\mu_B$/Yb.

**Figure 4** (online colour at: www.pss-b.com) Magnetic phase diagrams for the three single crystals with field $H \perp c$. The AFM phase boundary lines have been obtained by $T_-$ and $H$-dependent ac-susceptibility measurements (black and red solid lines) [45]; for Yb(Rh$_{0.93}$Co$_{0.07}$)$_2$Si$_2$, points detected from magnetization isotherms have been included (red diamonds). Circles correspond to the $T^*(H)$ line derived by the analysis of $M$ vs. $H$ (grey inside the AFM phase). Dotted lines are a guide to the eye. Inset: FWHM of the fit function (Eq. (1)). The solid lines are linear fits of the points located above $T_N$. 

![Graph](https://example.com/graph.png)
agreement with Ref. [27], but remains constant inside, suggesting either that such an analysis is valid only for $T \geq T_N(0)$, where it is not influenced by the ordered magnetic structure, or that the Fermi surface changes continuously at $T = 0$ inside the magnetic phase. The pronounced change of slope inside the AFM phase of the Yb(Rh0.93Co0.07)2Si2 sample was not seen in ac-susceptibility measurements where $H^*(0) \approx 0.06 \text{T}$ [3]. Our analysis of the magnetization provides $H^*(0) \approx 0.075 \text{T}$.

We discuss now the position of $H^*$ with respect to $H_N$ in YbRh2Si2. To detect the precise position of $H_N$ we have measured the $H$-dependence of the ac-susceptibility $\chi$ in the very same sample at temperatures below and above $T_N$. The results are shown in Fig. 5: At 20 mK, $\chi(H)$ displays a clear peak at $H_N \approx 50 \text{mT}$ and then decreases rapidly and continuously. This feature indicates a metamagnetic-like transition from the AFM to a PM state. The kink in $M(H)$ at about 0.1 T, which is in turn associated with the kink at $H^* \approx 0.05 \text{T}$ in $M(H)$, is the result of the rapid flattening of $\chi(H)$ with increasing $H$. No other anomalies are detected. Integrating the curve at 20 mK and plotting it together with the magnetization measured at 50 mK (inset of Fig. 5), we observe that the two curves match relatively well. From this analysis it can be inferred that $H_N < H^*$ in agreement with results from magnetotransport experiments [27]. Moreover, the red arrow in Fig. 5, which marks the position of $H^*$, points towards the point where the three susceptibility curves cross each other (isosbestic point [47]). This indicates that $d\chi(T)/dT = 0$ at $T^*$ in $\chi(T)$ [3]. The Maxwell relation $(\partial S/\partial H)_T = (\partial M/\partial T)_H$ implies that the field dependence of the entropy $S(H)$ has an inflection point at $H^*$ as it was demonstrated in Refs. [4, 48]. Thus, the $T^*(H)$ line defines the lines of $d^2S/dH^2 = 0$.

**3 Conclusions** To conclude, we have analysed magnetization isotherms of single crystals of YbRh2Si2, Yb(Rh0.94Ir0.06)2Si2 and Yb(Rh0.93Co0.07)2Si2 to indentify the position of the Fermi reconstruction crossover line $T^*(H)$ in the $H-T$ phase diagrams. We confirm that $T^*(H)$ is not much influenced by the Co and Ir isoelectronic substitution and that this line follows the points in the phase diagram where the entropy shows an inflection point. In the phase diagram of YbRh2Si2 this line is definitely located on the right of the AFM phase boundary line at the lowest temperatures. More importantly, in Yb(Rh0.93Co0.07)2Si2 the $T^*(H)$ line clearly falls inside the AFM phase and the FWHM of the crossover function remains almost constant inside the AFM phase while $T \rightarrow 0$, suggesting either that such an analysis is valid only for $T \geq T_N(0)$ or that the Fermi surface changes continuously at $T = 0$.
