Quantum coherence and distributed correlations among subparties are often considered as separate, although operationally linked to each other, properties of a quantum state. Here, we propose a measure able to quantify the contributions derived by both the tensor structure of the multipartite Hilbert space and the presence of coherence inside each of the subparties. Our results hold for any number of partitions of the Hilbert space. Within this unified framework, global coherence of the state is identified as the ingredient responsible for the presence of distributed quantum correlations, while local coherence also contributes to the quantumness of the state. A new quantifier, the “hookup”, is introduced within such a framework. We also provide a simple physical interpretation, in terms of coherence, of the difference between total correlations and the sum of classical and quantum correlations obtained using relative-entropy–based quantifiers.

1 Introduction

The superposition principle is one of the axioms and most distinctive features of quantum mechanics and it is responsible for the presence of coherence in quantum states [1]. When it comes to multipartite scenarios, the superposition principle is still the ingredient that makes quantum states intimately different from classical states and allows them to show inner correlations beyond any classical probabilistic model [2, 3, 4].

In the area of quantum information and quantum computation, there are many subfields where coherence and distributed correlations are seen as separate resources that enable quantum supremacy. For instance, let us consider the deterministic quantum computing with one qubit (DQC1) protocol, introduced by Knill and Laflamme [5]. It was argued in Ref. [6] that the quantum computational advantage may be due to the production of quantum discord. More recently, it was shown that any discord quantifier is a witness for recoverable coherence, whose presence is necessary for the protocol to be successful [7]. As a second example, a famous applications where the operational equivalence between local coherence and bipartite entanglement is quantum cryptography [8]. Indeed, the original BB84 key distribution scheme, which makes use of ordinary single-particle states in noncommuting bases [9], was proved to have the same security bounds as Ekert’s scheme, which relies on the use of maximally entangled states [10].

Despite the fact that coherence is one of the most distinctive traits of quantum mechanics, its characterization and quantification have only very recently become an intense field of investigation [11]. In analogy to what has been done in different contexts, such as entanglement theory ([2, 12, 13]) or quantum thermodynamics ([14, 15]), a resource theory for quantum coherence was proposed in Refs. [16, 17, 18, 19, 20, 21]. Coherence has also been linked to asymmetry [22, 23, 24] and purity [25]. The interplay between quantum correlations and coherence is mainly studied focusing on either the problem of interconversion between the two classes of resources [26, 27, 28, 29, 30] or the distribution of coherence among subparties and its monogamy properties [31, 32, 33, 34, 35, 36].

Given the fact that quantum correlations and coherences are both useful resources in quantum information and computing, it appears very relevant to find a way to completely characterize the overall computational power of a state exhibiting both aspects of quantumness through the introduction of a global quantifier (we will term...
it quantum hookup), which is the main scope of our paper. The way of pursuing this goal is represented by the introduction of a unified framework within which the full character of a quantum state belonging to a multipartite Hilbert space can be determined by both local and collective properties.

A unified framework was introduced in Ref. [37] trying to distinguish between total, classical, and quantum correlations (and also entanglement) as complementary parts of the same theoretical structure. In analogy to that approach, here we propose to merge the total power (the hookup) together with correlations and coherence in a consistent way. Within our framework, the concepts of classicality and quantumness need to be revisited. The founding observation to build the framework is that both coherence and correlations can be measured using the same kind of quantifier. We will make use of the quantum relative entropy, but different metrics, such as the $l_1$-norm could be introduced as well [18]. As we will show, not only is our scheme useful to give a comprehensive approach to quantummness through coherence, but it also allows one to explain the incongruent lack of closure emerging in the framework of Ref. [37], showing the indissoluble connexion between local and global quantum effects.

2 Definitions

Our starting point for quantifying correlations is the geometric scheme presented in Ref. [37]. All the distances between pairs of states $\rho$ and $\sigma$ are measured by the quantum relative entropy $S(\rho||\sigma) = -\text{tr}\{\rho \log \sigma\} - S(\rho)$, where $S(\rho) = -\text{tr}\{\rho \log \rho\}$ is the von Neumann entropy of $\rho$. The relative entropy, in spite of its lack of symmetry, is commonly used and accepted as a distance measure in different contexts, as it fulfils a series of important requirements [38]: it is a positive definite directed measure of the distance between two states; it is contractive under completely positive and trace-preserving maps; its explicit calculation is feasible in various common scenarios; it avoids possible inconsistencies in the definition of discord [39, 40].

Within this approach, the various kinds of correlations present in a quantum state are quantified by the distance between the state itself and the closest state without the desired property. Thus, the total correlations of a multipartite state $\rho \equiv \rho_{A_1 A_2 \cdots A_n}$ are given by the distance from the closest product state. Total correlations are quantified by the total mutual information of that state:

$$T(\rho) = S(\rho || \pi[\rho]) = S(\pi[\rho]) - S(\rho),$$

(1)

with $\pi[\rho] = \pi_{A_1} \otimes \cdots \otimes \pi_{A_n}$ where $\pi_{A_i}$ is obtained from $\rho$ calculating the partial trace over all the partitions with the exception of the $i$th. The quantum part of these correlations is measured by the (two-sided, relative entropy of) quantum discord [37]

$$D(\rho) = S(\rho || \chi_\rho) = S(\chi_\rho) - S(\rho),$$

(2)

where $\chi_\rho$ is the classically correlated state closest to $\rho$ and where classically correlated states are separable in the $n$-partite Hilbert space:

$$\chi = \sum_k p_k |\vec{k}\rangle \langle \vec{k}|,$n, with $|\vec{k}\rangle = |k_1\rangle \otimes \cdots \otimes |k_n\rangle.$

(3)

The basis is given by product states, as the use of a nonlocal entangled basis would somehow hide the quantumness of the states within the basis itself. In turn, classical correlations of $\rho$ (and equivalently of $\chi_\rho$) are given by

$$J(\rho) = S(\chi_\rho || \pi[\chi_\rho]) = S(\pi[\chi_\rho]) - S(\chi_\rho),$$

(4)

where $\pi[\chi_\rho]$ is the product (uncorrelated) state closest to $\chi_\rho$ [37]. Within this treatment, an incongruity comes out, as in general the sum of classical plus quantum correlations exceeds the total correlations: $T(\rho) \leq D(\rho) + J(\rho)$, with the equality holding only in some special cases. In fact, we have [37]

$$L(\rho) \equiv D(\rho) + J(\rho) - T(\rho) = S(\pi[\rho] || \pi[\chi_\rho]).$$

(5)

As we shall see later, we are able to give a physical interpretation for $L(\rho)$ in terms of the quantum coherence of the local sub-parties. Here, it is worth remarking that, in this context, $\chi_\rho$ is commonly referred as “the classical state closest to $\rho$” [37, 41, 42]. Within a unified framework, $\chi_\rho$ more specifically identifies a classically correlated state that can be coherent or not. Indeed there is only one special basis where its coherence vanishes and where it can be seen as
a fully classical entity. Otherwise, a state exhibiting nonvanishing nondiagonal density-matrix elements can hardly be considered as a classical one but could be classically correlated.

In analogy with correlations, also coherence can be quantified using the relative entropy [18, 43]. The relative entropy of coherence of a state $\rho$ with respect to a basis is defined as

$$C(\rho) = \min_{\sigma \in \mathcal{I}} S(\rho||\sigma),$$

where $\mathcal{I}$ is the set of totally incoherent (diagonal) states in that basis. In general this definition is independent of possible partitions of the Hilbert space and, even for multipartite systems the basis could be local or nonlocal. It turns out that $C(\rho) = S(\rho||\Delta(\rho)) = S(\rho) - S(\Delta(\rho))$, where $\Delta$ is the full decohering operation, leading to a state with all the non-diagonal elements of $\rho$ set to zero [18]. The dependence on the basis choice will not explicitly appear in the notation of $C, \rho$ or other coherence related indicators. Henceforth, unless specifically indicated, states will always be represented in product bases as in (3). In particular, $\Delta[\rho] = \sum |\tilde{k}\rangle\langle\tilde{k}|\rho\langle\tilde{k}|\tilde{k}\rangle$.

### 3 Results

As mentioned in the introduction, the distribution of coherence in multipartite settings has been subject of recent interest [32, 33, 34, 35]. Building on these results, it is useful to introduce the concept of local coherence that is present in the state $\pi(\rho)$ to be distinguished from genuine multipartite effects [32, 35]. In the framework of relative entropy, the local coherence of a state $\rho_{A_1,A_2,\ldots,A_n}$ is the sum of the coherences of the reduced states $\pi_{A_i}$:

$$C_L(\rho) = \sum_{i=1}^n C(\pi_{A_i}),$$

with $C$ defined in Eq. (6). Using the additivity of the relative entropy, it can be shown that the following equality holds:

$$C_L(\rho) = S(\pi[\rho]|\Delta[\pi[\rho]]).$$

In the same framework, a measure for the genuinely multipartite contribution to coherence can be introduced by subtracting the contribution of local terms (see also Ref. [44]):

$$C_M(\rho) = C(\rho) - C_L(\rho).$$

It can be shown that $C_M(\rho)$ is a nonnegative quantity, and, for this purpose we anticipate the following [see also the illustration in Fig. 1(a)]:

**Lemma 1** The total dephasing operation $\Delta[\cdot]$ commutes with $\pi[\cdot]$, that is, $\Delta[\pi[\rho]] = \pi[\Delta[\rho]]$.

**Proof** The proof can be given by calculating explicitly the matrix elements of the two operators. Given a generic bipartite state (the proof is identical irrespective of the number of parties) $\rho = \sum_{i,j,k,l} c_{i,j,k,l}\langle i,j|k,l\rangle$, we have $\Delta[\rho] = \sum_{i,j} c_{i,j}\langle i,j|i,j\rangle$ and $\pi[\rho] = \sum_{i,j,k} c_{i,j,k}\langle i,j|k\rangle$. Thus, for both operators we have $\Delta[\pi[\rho]] = \pi[\Delta[\rho]] = \sum_{i,j} c_{i,j}\langle i|\sum_{i,j} c_{i,j}\langle i|j\rangle$.

The nonnegativity of $C_M(\rho)$, that is, the hierarchical relationship $C(\rho) \geq C_L(\rho)$, can be proved by using the fact that $C(\rho)$ is the relative entropy between two states $|\rho$ and $\sigma$ in (6), while $C_L(\rho)$ is the relative entropy between two new states obtained from the previous ones by applying the quantum operation $\pi$ and by using **Lemma 1** in Eq. (8). We have

$$C_M(\rho) = S(\rho||\Delta(\rho)) - S(\pi[\rho]||\pi[\Delta[\rho]])$$

![Figure 1](image-url)
Given a state $\rho$, its closest incoherent product state is obtained by applying the dephasing operation to $\pi[\rho]$:  
$$
\mathcal{M}(\rho) = S(\rho|\Delta[\pi[\rho]]).
$$

**Theorem 2** Given a state $\rho$, its closest incoherent product state is obtained by applying the dephasing operation to $\pi[\rho]$:  
$$
\mathcal{M}(\rho) = S(\rho|\Delta[\pi[\rho]]).
$$

**Proof** The relative entropy between $\rho$ and any incoherent state $\sigma$ can be written as $S(\rho||\sigma) = S(\Delta[\rho]) - S(\rho) + S(\Delta[\rho]|\sigma)$. The product state closest to $\Delta[\rho]$ is $\pi[\Delta[\rho]]$ [37], or, using **Lemma 1**, $\Delta[\pi[\rho]]$. Thus, $S(\rho||\sigma) = S(\Delta[\pi[\rho]]) - S(\rho) = \mathcal{M}(\rho)$, where the equality holds for $\sigma = \Delta[\pi[\rho]]$.  

Beyond the geometric definition of the hookup $\mathcal{M}$ (12), a clear physical interpretation can be given observing that it can be decomposed as the sum of two terms, one of them associated to multipartite correlations $|T(\rho)|$ and the other one being, according to Eq. (7), the local coherence of the state $C_L(\rho)$ [see Fig. 1(a)]  
$$
\mathcal{M}(\rho) = T(\rho) + C_L(\rho).
$$

In other words, $\mathcal{M}$ is able to capture the resources of both correlations across the multipartite system and of the local coherences [Eq. (14)]. Using Eq. (5) we can also decompose the hookup as  
$$
\mathcal{M}(\rho) = D(\rho) + J(\rho) + C_L(\rho) - L(\rho).
$$

Exploiting **Lemma 1**, a different decomposition of $\mathcal{M}$ can be given where the total coherence appears explicitly. In fact, we have [see Fig. 1(a)]  
$$
\mathcal{M}(\rho) = C(\rho) + \mathcal{K}(\rho),
$$

where also the totally classical correlations $\mathcal{K}(\rho) \equiv T(\Delta[\rho])$ appear. The quantity $\mathcal{K}(\rho)$, measuring total correlations of the diagonal ensemble, naturally emerges in our unified framework. Interestingly it has already been proved to play a relevant role in the context of many-body localization and quantum ergodicity [49]. It quantifies the amount of information that survives to total dephasing and is given by the classical mutual information of $\rho$. It is a purely classical object, as it obtained by eliminating both quantum correlations and coherence. Thus, we will call $\mathcal{K}$ *irreducible* classical information. It can also be written as $\mathcal{K} = T - C_M$ [see (11)].

Equation (16) redefines a different separation between the classical and the quantum part of resources with respect to (14). Indeed, the quantum content of the state is all contained in the total coherence $C$, which is an upper bound for quantum discord. In fact, as already noticed in...
Ref. [33], $D(\rho)$ is the minimum value of coherence calculated over all the possible local unitaries $U_{\text{loc}} = U_1 \otimes U_2 \otimes \cdots \otimes U_n$ [see the upper distances in Fig. 1(b)]. In other words, total coherence is minimized in the basis where $\chi_\rho$ is completely incoherent ($\chi_\rho = \mathbf{\Delta}[\rho]$, where the bar reminds the special choice of basis adopted here). This result can be understood observing that incoherent states are a sub-ensemble of the family of classical states. As a consequence, $\mathbf{\Delta}[\rho]$ is the closest state to $\rho$ which is completely classical, from the point of view of both coherence and correlations. Then, in the basis of the eigenstates of $\chi_\rho$, $\chi_\rho \equiv \mathbf{\Delta}[\rho]$, and $D(\rho) = \mathcal{C}(\rho)$. In such a special basis, classical and irreducible classical correlations become equal as it will be shown below.

While $J$ is expected to measure the amount of correlations that can be described within a classical probability model but does not take into account the freedom of changing the reference basis, which is a fully quantum property, $K$ catches both aspects of classicality, that is, the absence of quantum correlations and the lack of coherence. The different definitions of $J$ and $K$ suggest a possible hierarchical relationship $J \geq K$. Actually, as explicitly shown in an example in Appendix A, this is not true. This is related to the mentioned lack of closure of Modi’s scheme of correlations [37] [see Eq. (5)], which may cause a bad estimation of classicality.

Interestingly, the excess term $L(\rho)$ admits a clear physical interpretation within our framework. Indeed, let us consider the case where $\rho$ is written in the basis of the eigenstates of $\chi_\rho$. In that basis, according to what said before, $\chi_\rho = \mathbf{\Delta}[\rho]$. Consequently, by applying Lemma 1 and Eq. (5),

$$L(\rho) = S(\mathbf{\Delta}[\pi[\rho]]) - S(\pi[\rho]) \equiv \mathcal{C}_L(\rho),$$

where again the bar reminds the special basis choice here. This allows one to see that, as anticipated before, in the basis where the classical state $\chi_\rho$ is incoherent, the hookup turns out to be the sum of discord and classical correlations $\mathcal{M}(\rho) = D(\rho) + J(\rho)$.

The main consequence of Eq. (17) is that a unified framework of correlations and coherences allows for a physical interpretation of $L$ as the local coherence of $\rho$ calculated in the basis where $\chi_\rho$ can be considered sensu stricto classical. It is always possible to find a (classical) basis where $\mathcal{C}_L = 0$ (such a basis is just the basis of the eigenvectors of $\pi(\rho)$). Then, a nonvanishing value of $L$ implies that the basis that minimizes the total coherence is a different one. It can be interpreted as a basis mismatch measure and represents the lack of completeness of the correlation framework, as it tries to quantify quantumness by omitting the conceptually fundamental component of local coherence.

In order to understand the consequences of Eq. (16), let us discuss a simple example and consider the two-qubit state $\rho = \frac{1}{4} |\Phi^+\rangle\langle\Phi^+| + \frac{1}{4} |01\rangle\langle01| + \frac{1}{4} |10\rangle\langle10|$, where $|\Phi^+\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$ in the computational basis. The closest incoherent state is the identity operator $\mathbb{I}/4$, which is obviously completely uncorrelated. This implies that for such a state $\mathcal{M} = C = C_M = 0.5$, while $K = 0$. Thus, all the usable resources are contained in the coherences of the Bell state and have a purely quantum nature, while there is no classical contribution to them. The state has finite classical correlations $J(\rho) \simeq 0.19$, obtained by applying the decohering operator in the rotated $x$ basis, which gives $\chi_\rho = \mathbb{I}/4 + (|00\rangle\langle11| + |10\rangle\langle01| + h.c.)/8$, but all these correlations are due to the initial presence of multipartite coherence. In fact, also the coherence of $\chi_\rho$ is genuinely multipartite: $J(\chi_\rho) = C(\chi_\rho) = C_M(\chi_\rho)$. We point out that this example shows that the coherence of a classically correlated state can be (even completely) multipartite. Furthermore, discord (here $\mathcal{D}(\rho) \simeq 0.31$) can be present even for vanishing irreducible classical correlations, at difference from the classical ones [50].

Previously, we have commented on the lack of hierarchy between $K$ and $J$. As a complementary aspect, the same lack of hierarchy takes place between $L$ and $\mathcal{C}_L$. The case $\mathcal{C}_L \geq L$ can be found considering for instance any pure state, as $L = 0$ (in fact, the optimal dephasing basis to find $\chi$ is always the basis of the eigenstates of the state itself). A case where this ordering relationship is violated can be found by considering the state $\psi = \frac{8}{27} |000\rangle(000) + \frac{12}{27} |W\rangle(000) + \frac{6}{27} |\tilde{W}\rangle(000) + \frac{1}{27} |011\rangle(111)$ [51], where $|\tilde{W}\rangle = \frac{1}{\sqrt{3}} (|011\rangle + |110\rangle + |101\rangle)$. In fact, we have $L(\psi) = 0.24$ [37]. It can immediately checked that the local coherence vanishes in the computational basis and it can also be shown that $\mathcal{C}_L(\psi) \leq L(\psi)$ for any local basis change.
Finally, let us mention that, apart from the relationship between discord and coherence, which are both indicators of overall quantumness, it is also possible to establish a similar one between the purely multiparticle coherence $C_M(\rho_{A_1,\ldots,A_n})$ and an indicator of genuine quantum correlations, the so called global discord $G(\rho_{A_1,\ldots,A_n})$ [52], defined as 
\[ G(\rho_{A_1,\ldots,A_n}) = \min_{U_{loc}} G(\rho) \]
where $G(\rho) = \min_{U_{loc}} C_M(\rho)$, (18)
where the minimum is taken over the set local unitaries.

4 Conclusions

To summarize, when it comes to characterize a quantum state, the (total) mutual information is not necessarily an adequate indicator, for it fails to take into account the coherence properties of the state itself. This is the reason why the puzzling term $L(\rho)$ comes out in the relative entropy framework. Such a term can be taken as a witness of the fact that the local coherence and the global one are minimized in different bases. This seemingly side observation actually reveals how much a unified framework is needed to build a consistent theory.

In the approach proposed here, quantum coherence and multipartite correlations cannot be thought as distinct labels, as they both contribute to hallmark the state, providing a full description of its quantumness. We have introduced the hookup $\mathcal{M}$ and shown that it amounts to the sum of coherence and irreducible classical information resources or equivalently to the sum of local coherence and total correlations. Such a comprehensive hallmark has different conceivable applications, as it fully determines the power of a quantum state. As previously mentioned, the hookup $\mathcal{M}$ can be used to measure the amount of work necessary to erase such correlations and has obvious thermodynamic implications that can be further explored, for instance in the field of ergotropy. The interplay between quantum local and distributed contributions could also be employed in computing tasks, as the algorithmic performances are studied by analyzing either the single-qubit power or the presence of correlations as entanglement or discord. Another field where correlations and coherence are separately essential resources is quantum metrology, where our approach can be used to find the optimal quantum advantage and tighter bounds. A possible extension of our framework could concern the use of entanglement to quantify the multipartite quantumness instead of discord. In this case, the main obstacle is represented by the difficulty to define the closest unentangled state in terms of elementary operation, as the partial trace or the total dephasing. Finally, a further line of research that a unified framework can open concerns the possibility of converting different types of resources among them [29, 30].

A Comparison between $\mathcal{K}$ and $\mathcal{J}$

As an instructive example of the lack of hierarchy between $\mathcal{K}$ and $\mathcal{J}$, let us consider the maximally discordant mixed state $\tilde{\rho}_{MD} = \epsilon(\Phi^+)\langle \Phi^+ | + (1-\epsilon)|10\rangle\langle 10 |$ (the choice is suggested by the fact that this state is known to have low classical correlations compared to discord) [50], together with the whole family of states obtained by applying local unitaries. Such a family is given by $\tilde{\rho}_{MD} = U_\epsilon \tilde{\rho}_{MD} U_\epsilon^\dagger$, where the most general form for $U$ is $U = U_1 \otimes U_2$ with
\[ U_j = \left( \begin{array}{cc} \cos \theta_j & e^{i\phi_j} \sin \theta_j \\ -e^{-i\phi_j} \sin \theta_j & \cos \theta_j \end{array} \right). \] (19)
The state is symmetric under the exchange of the two qubits up to the spin-flip operation. Such
a symmetry is reflected into the extremal values assumed by the angles $\theta_j$ in optimal measurements \[53\], as calculating the von Neumann entropy of $\tilde{\rho}_{MD}$ amounts to calculating the entropy of $\rho_{MD}$ in a rotated basis obtained by applying the unitary $U^\dagger$ to the set of computational states. Thus, the set of optimal values is restricted to $\theta_1 = \theta_2 \equiv \theta$ and $\phi_1 = -\phi_2$. It can be further shown that the result is independent on the phases, provided that $\phi_1 = -\phi_2$, and then they can be fixed to zero.

Depending on the value of $\epsilon$, the closest classically correlated state $\chi_{\tilde{\rho}_{MD}}$ is obtained by dephasing $\rho_{MD}$ either in the computational basis for $\epsilon < \epsilon'$ or in a rotated basis for $\epsilon > \epsilon'$, where the threshold is given by $\epsilon' = 2/3$. Above a second threshold, for $\epsilon > \epsilon'' \simeq 0.76$, the optimal basis is the $x$-basis. On the other hand, $K$ reaches its maximum in the $x$-basis irrespective of $\epsilon$. This means that, for $\epsilon < \epsilon''$, $K(\tilde{\rho}_{MD})$ can be either bigger or smaller than $J(\tilde{\rho}_{MD})$ depending on the unitary chosen, while $K(\tilde{\rho}_{MD}) \leq J(\rho_{MD})$ for $\epsilon > \epsilon''$. As for the hookup $M$, it always reaches its maximum in the $x$-basis and its minimum in the computational basis.

In Fig. 2, we compare $J$ and $K$. The analytical values of $\epsilon'$ and $\epsilon''$ can be obtained by solving, respectively, the equations

\[
\lim_{\theta \to 0} \frac{\partial^2 S(\tilde{\rho}_{MD})}{\partial \epsilon^2} = 0, \quad (20)
\]

\[
\lim_{\theta \to \pi/4} \frac{\partial^2 S(\tilde{\rho}_{MD})}{\partial \epsilon^2} = 0. \quad (21)
\]

Figure 2: Comparison between $J$ (red) and $K$ (blue) for the family $\tilde{\rho}_{MD}$ as a function of $\theta$ and $\epsilon$. $J$ is an upper bound for $K(\theta)$ only in the region $\epsilon'' < \epsilon < 1$ (see text).
