ABSTRACT

Core radii of globular clusters in the Large and Small Magellanic Clouds show an increasing trend with age. We propose that this trend is a dynamical effect resulting from the accumulation of massive stars and stellar-mass black holes at the cluster centers. The black holes are remnants of stars with initial masses exceeding \( \sim 20 \)–25 \( M_\odot \); as their orbits decay by dynamical friction, they heat the stellar background and create a core. Using analytical estimates and \( N \)-body experiments, we show that the sizes of the cores so produced and their growth rates are consistent with what is observed. We propose that this mechanism is responsible for the formation of cores in all globular clusters and possibly in other systems as well.

Subject headings: black hole physics — galaxies: nuclei — gravitation — gravitational waves

1. INTRODUCTION

An enduring problem is the origin of cores, regions near the center of a stellar or dark matter system where the density is nearly constant. Resolved cores clearly exist in some stellar systems, e.g., globular clusters (GCs; Harris 1996). In other systems, such as early-type galaxies, cores were long believed to be generic but were later shown to be artifacts of the seeing (Schweizer 1979). Nevertheless, a few elliptical galaxies do exhibit bona fide cores (Lauer et al. 2002), while many others show a central density that rises only very slowly toward the center (Merritt & Fridman 1995). Density profiles of structures that form from gravitational clustering of density perturbations in an expanding universe are believed to lack cores (Power et al. 2003), although there is evidence for dark matter cores in the rotation curves of some late-type galaxies (e.g., Jimenez et al. 2003).

The existence of a core is usually deemed to require a special explanation. For instance, galaxy cores may form when binary black holes eject stars via the gravitational slingshot (Ebisuzaki et al. 1991).

A useful sample for testing theories of core formation is the ensemble of GCs around the Large and Small Magellanic Clouds (LMC/SMC). These clusters have masses similar to those of Galactic GCs, but many are much younger, with ages that range from \( 10^6 \) to \( 10^9 \) yr. Furthermore, ground-based (Elson et al. 1989; Elson 1991, 1992) and \textit{Hubble Space Telescope} (Mackey & Gilmore 2003a, 2003b) observations reveal a clear trend of core size on age in the LMC/SMC clusters. The idea that the core size varies as a function of age is consistent with the observed dependence of core size on age in the LMC/SMC clusters. The idea that the core structure of GCs is controlled by a population of massive remnants was first proposed by Larson (1984).

2. CORE FORMATION TIMESCALES

Consider a gravitationally bound stellar system in which most of the mass is in the form of stars of mass \( m \) but which also contains a subpopulation of more massive objects with masses \( m_{\text{BH}} \). The orbits of the more massive objects decay because of dynamical friction. Assume that the stellar density profile is initially a power law in radius, \( \rho(r) = K(r/a)^{-\gamma} \), \( K = (3 - \gamma)M/4\pi a^3 \), with \( M \) the total stellar mass and \( a \) the density scale length; the expression for \( K \) assumes that the density follows a Dehnen (1993) law outside of the stellar cusp, i.e., \( \rho \sim r^{-\gamma} \) at large \( r \). The effective radius (the radius containing \( \frac{1}{2} \) of the mass in projection) is related to \( a \) via \( R_{\text{eff}}/a \approx (1.8, 1.3, 1.0) \) for \( \gamma = (1, 1.5, 2) \).

Because of the high central concentration of the mass, the orbits of the massive particles will rapidly circularize as they receive nearly impulsive velocity changes near pericenter. Once circular, orbits shrink at a rate that can be computed by equating the torque from dynamical friction with the rate of change of orbital angular momentum. We adopt the usual approximation (Spitzer 1987) in which the frictional force is produced by stars with velocities less than the orbital velocity of the massive
object. The rate of change of the orbital radius, assuming a fixed and isotropic stellar background, is then

$$\frac{dr}{dt} = -2 \frac{3 - \gamma}{4 - \gamma} \sqrt{\frac{GM}{a} m_{\text{BH}}} \ln \Lambda \left( \frac{r}{a} \right)^{\gamma/2} F(\gamma),$$

$$F(\gamma) = \frac{2^\beta}{\sqrt{2}\pi} \Gamma(\beta - 3/2) \int_0^1 dy y^{1/2} (y + \frac{2}{2 - \gamma})^{-\beta},$$

where $\beta = (6 - \gamma)/2(2 - \gamma)$ and $\ln \Lambda$ is the Coulomb logarithm, roughly equal to 6.6 (Spinnato et al. 2003). For $\gamma = (1.0, 1.5, 2.0)$, $F = (0.193, 0.302, 0.427)$. Equation (1) implies that the massive object comes to rest at the center of the stellar system in a time

$$\Delta t \approx 0.2 \sqrt{\frac{a}{GM m_{\text{BH}}}} \left( \frac{r}{a} \right)^{(6 - \gamma)/2},$$

with $r$ the initial orbital radius; the leading coefficient depends weakly on $\gamma$. Equation (2) can be written

$$\Delta t \approx 3 \times 10^9 \text{yr} a_{10}^{3/2} M_{10}^{1/2} m_{\text{BH},10}^{-1} \left( \frac{r}{a} \right)^{(6 - \gamma)/2},$$

with $a_{10}$ the density scale length in units of 10 pc (e.g., Fig. 1 of van den Bergh 1991), $M_\odot = M/10^5 M_\odot$, and $m_{\text{BH},10} = m_{\text{BH}}/10 M_\odot$, the approximate masses of black hole remnants of stars with initial masses exceeding $\sim 20 - 25 M_\odot$ (Maeder 1992; Portegies Zwart et al. 1997). This time is of the same order as the time ($\sim 10^9$ yr) over which core expansion is observed to take place (Mackey & Gilmore 2003a, 2003b; Fig. 1).

To estimate the effect of the massive remnants on the stellar density profile, consider the evolution of an ensemble of massive particles in a stellar system with initial density profile $\rho \sim r^{-2}$. The energy released as one particle spirals in from radius $r_0$ to $r_1$ is $2m_{\text{BH}} a^2 \ln (r_1/r_0)$, with $a$ the one-dimensional stellar velocity dispersion. Decay will halt when the massive particles form a self-gravitating system of radius $\sim GM_{\text{BH}}/a^2$ with $M_{\text{BH}} = \sum m_{\text{BH}}$. (A condition for the more massive component to become self-gravitating is given by Watters et al. 2000; the N-body models presented below satisfy this condition.) Equating the energy released during infall with the energy of the stellar matter initially within $r_c$, the “core radius,” gives

$$r_c \approx \frac{2GM_{\text{BH}}}{a^2} \ln \left( \frac{r_c^2}{GM_{\text{BH}}} \right).$$

Most of the massive particles that deposit their energy within $r_c$ will come from radii $r_0$, implying that $r_c \approx \sum m_{\text{BH}} a^2 / 2$ and a displaced stellar mass of $\sim \text{several} \times M_{\text{BH}}$. If $M_{\text{BH}} \approx 10^{-3} M_\odot$ (Portegies Zwart & McMillan 2000), then $r_c/a \approx \text{several} \times 2M_{\text{BH}}/M$ and the core radius is roughly 10% of the effective radius.

Evolution continues as the massive particles form binaries and begin to engage in three-body interactions with other massive particles. These superelastic encounters will eventually eject most or all of the massive particles from the cluster. Assume that this ejection occurs via the cumulative effect of many encounters, such that almost all of the binding energy so released can find its way into the stellar system as the particle spirals back into the core. The energy released by a single binary in shrinking to a separation such that its orbital velocity equals the escape velocity from the core is $\sim m_{\text{BH}} a^2 \ln (4M_{\text{BH}}/M)$. If all of the massive particles find themselves in such binaries before their final ejection, and if most of their energy is deposited near the center of the stellar system, the additional core mass will be

$$M_c \approx m_{\text{BH}} \ln \frac{M}{M_{\text{BH}}},$$

e.g., $\sim 5M_{\text{BH}}$ for $M/M_{\text{BH}} = 100$, similar to the mass displaced by the initial infall. The additional mass displacement takes place over a much longer timescale, however, and additional processes (e.g., core collapse) may compete with it.

3. N-BODY SIMULATIONS

We used N-body simulations to test the core formation mechanism described above. Integrations were carried out using NBODY6++, a high-precision, parallel, fourth-order direct force integrator that implements coordinate regularization for close encounters (Spurzem 1999). Particles had one of two masses, representing either black holes ($m_{\text{BH}}$) or stars ($m$). The number of particles representing black hole masses was $N_{\text{BH}} = (4, 10, 20)$, and the ratio of $m_{\text{BH}}$ to $m$ ranged from 10 to 25. Most of the N-body experiments used $N = 10^4$ particles. We concentrate here on the results obtained with $N_{\text{BH}} = 10$ and $m_{\text{BH}}/m = 10$; results obtained with other values of $N_{\text{BH}}$ were consistent. All particles were initially distributed according to Dehnen’s (1993) density law,

$$\rho(r) = [(3 - \gamma)M/4\pi a^3] / r^{1+\xi}, \xi = r/a, \text{with isotropic velocities.}$$

The mass fraction in massive particles was set at 1%, based on a Scala (1986) mass distribution with lower and upper mass limits of 0.1 and 100 $M_\odot$, respectively. With such a mass function, about 0.071% of the stars are more massive than 20 $M_\odot$.
and 0.045% are more massive than 25 $M_\odot$. A star cluster containing $N_\star$ stars thus produces $\sim 6 \times 10^{-3} N_\star$ black holes. Known Galactic black holes have masses $m_{\text{BH}}$ between 6 and 18 $M_\odot$ (McClintock & Remillard 2004). Adopting an average black hole mass of 10 $M_\odot$ then results in a total black hole mass of $\sim 6 \times 10^{-3} M$. The use of just two mass groups is a simplifying idealization, since both the stars and the more massive remnants would exhibit a mass spectrum.

If the core radius is defined as the radius at which the projected density falls to $\frac{1}{2}$ of its central value, Dehnen models (Dehnen 1993, 1998) illustrated this is via the $r_h$ parameter, integrated from the origin out to the radius at which the density at time $t$ falls to $\frac{1}{2}$ of its central value. Each curve is the average of the various experiments at the specified value of $\gamma$, with $\gamma = 0.5$ (top), $\gamma = 1$ (middle), and $\gamma = 2$ (bottom). Vertical axis is in units such that the Dehnen model scale length $a = 1$; see text for conversion factors from $a$ to $R_c$.

Henceforth we adopt units in which $G = a = M = 1$. The corresponding unit of time is

$$[T] = \left[ \frac{GM}{a} \right]^{1/2} = 1.44 \times 10^6 \ \text{yr}(M_5^{-1/2}a_{10}^{3/2}),$$

(6)

where $M_5$ is the cluster mass in units of $10^5 M_\odot$ and $a_{10}$ is the cluster scale length in units of 10 pc. The effective radius $R_e$, defined as the radius containing $\frac{1}{2}$ of the light particles seen in projection, is $R_e \approx (1.8, 1.3, 1.0)$ in model units ($a = 1$) for $\gamma = (1, 1.5, 2)$. The time scaling of equation (6) is not correct for processes whose rates depend on the masses of individual stars or black holes, since our models have fewer stars than real GCs. The most important of these processes for our purposes are black hole–star interactions, which are responsible for the orbital decay of the black holes and the growth of the core. This decay occurs in our simulations at a rate that is $\sim N_\bullet / N_{\text{BH}}$ times faster than implied by the scaling of equation (6), with $N_\bullet$ the true number of black holes in a GC. Assuming a Scalo initial mass function as above, this factor may be written $-6.0(N_\star/10^5)/(N_{\text{BH}}/10)$ with $N_\star$ the true number of stars in a GC.

As discussed above, we expect the stellar mass displaced by the massive particles to scale roughly with $M_{\text{BH}}$. One way to illustrate this is via the mass deficit (or “core mass”), defined as in Milosavljević et al. (2002): it is the mass difference between the initial stellar density $\rho(r, 0)$ and the density at time $t$, integrated from the origin out to the radius at which $\rho(r, t)$ first exceeds $\rho(r, 0)$. Figure 2 shows $M_{\text{def}}(t)/M_{\text{BH}}$ for the $N$-body experiments. The density center was computed via the Cercignani & Hut (1985) algorithm. The black holes displace a mass in stars of the order of 1–8 times their own mass; the larger values correspond to the larger values of $\gamma$ although there is considerable scatter from experiment to experiment for a given $\gamma$. The results for $\gamma = 2$ are consistent with the analytic arguments presented above, which implied a core mass of a few times $M_{\text{BH}}$ after a time in model units of $\sim 0.2 M_{\text{BH}}$ (cf. eq. [2]) followed by a slower displacement of a similar mass as the black hole particles engage in three-body interactions (cf. eq. [5]).

Some of the $N$-body simulations show a decrease in the core radius after $t \approx 10^5$ (Figs. 2 and 3). By this time, the majority of the black holes have been ejected. Our simulated clusters are then effectively reduced to equal-mass systems, which take about 15 half-mass relaxation times to experience core collapse (Spitzer 1987). The two-body relaxation time is roughly $T_{\text{rel}} \approx 0.2 T_{e}/N \ln N \approx 200$ in our $N$-body models, with $T_{e}$ the crossing time. It is therefore not surprising that once the black holes are ejected, the cluster core shrinks again on a timescale of $\sim 10^3$ time units.

Figure 3 shows the evolution of the core radii in these simulations. Computation of $r_c$ was based on its standard definition as the projected radius at which the surface density falls to $\frac{1}{2}$ of its central value. To reduce the noise, values of $r_c$ from all
experiments with the same γ and with \( N_{\text{BH}} = 10 \) were averaged together. Figure 3 shows that core sizes increase roughly as the logarithm of the time, consistent with the time dependence of the upper envelope of Figure 1, and reach values at the end of the simulations of \( \sim 10 \% \) of the half-mass radius.

On the basis of equation (6) and the discussion following, the conversion factor from model time units to physical time units is approximately

\[
8.9 \times 10^6 \text{yr}(M_5^{1/2}a_{10}^{1/2}N_{*,5}),
\]

with \( N_{*,5} \) the number of stars in the GC in units of \( 10^5 \). This scaling was used to plot three curves in Figure 1: with \( M_5 = N_{*,5} = 2, a_{10} = 0.5 \) (bottom), \( M_5 = N_{*,5} = 0.5, a_{10} = 1 \) (middle), and \( M_5 = N_{*,5} = 1, a_{10} = 2.5 \) (top). (The largest \( R_c \) of any galactic GC is about 25 pc.) The curves in Figure 1 were taken from the experiments with \( \gamma = 1 \); the experiments with \( \gamma = 1.5 \) and 2 give similar results (note that \( R_c/a \) varies by a factor of \( \sim 2 \) from \( \gamma = 1 \) to 2, hence \( r/R \) varies less than \( r/a \) in Fig. 3). The logarithmic time dependence of the upper envelope of the \( r \) distribution is well reproduced, and with appropriate (and reasonable) scaling, points below the envelope can also be matched. As noted above, the smaller core radii that begin to appear in SMC/LMC clusters with \( \tau \approx 10^7 \text{yr} \) are plausibly due to evolution toward core collapse in these clusters, as seen also in some of the simulations.

4. DISCUSSION

The core formation mechanism proposed here could begin to act even before the most massive stars had evolved into black holes. Evolution times for 20 \( M_\odot \) stars are \( \sim 8 \text{Myr} \) (Schaller et al. 1992). The earliest phases of core formation, \( \tau \approx 10^7 \text{yr} \), would therefore be driven by the accumulation of massive stars rather than by their remnants. Figure 1 shows possible evidence of core growth on timescales \( \approx 20 \text{Myr} \) in a few clusters. In this context it is interesting to mention the so-called young dense star clusters. These clusters have ages \( \leq 10 \text{Myr} \) and sizes \( \sim 1 \text{ pc} \) and contain \( \leq 10^5 \text{ stars} \). Well-known examples are NGC 2070 (Brandl et al. 1996), NGC 3603 (Vrba et al. 2000), and Westerlund 1 (Brandl et al. 1999). All of these young clusters have small but distinct cores. The young cluster R136 in 30 Doradus (\( \tau \approx 5 \text{Myr} \)) shows clear evidence of mass segregation among the brightest stars (Brandl et al. 1996).

In galactic nuclei, the imprints left on the stellar distribution by the clustering of stellar-mass black holes were probably long ago erased by the growth of the supermassive black hole, by the formation and decay of binary supermassive black holes during galaxy mergers, and by star formation.

A speculative application of these results is to cores formed at the centers of dark matter halos by the clustering of Population III remnants in the early universe (Volonteri et al. 2003). The latter are believed to contain at least \( \frac{1}{2} \) the mass of their stellar progenitors when \( m \approx 250 M_\odot \) (Fryer et al. 2001), and the cosmological density of remnants may be similar to that of the supermassive black holes currently observed at the centers of galaxies (Madau & Rees 2001). It follows that the Population III remnants could create cores of appreciable size, if a number of them can accumulate in a single halo at a given time, and if the time for their orbits to decay is shorter than the time between halo mergers. Both propositions will require further investigation.
