ABSTRACT
The Gould Belt Legacy Survey will survey nearby star-forming regions (within 500 pc), using Heterodyne Array Receiver Programme (HARP), Submillimetre Common-User Bolometer Array 2 and Polarimeter 2 on the James Clerk Maxwell Telescope. This paper describes the initial data obtained using HARP to observe $^{12}$CO, $^{13}$CO and C$^{18}$O $J = 3 \rightarrow 2$ towards two regions in Orion B, NGC 2024 and NGC 2071. We describe the physical characteristics of the two clouds, calculating temperatures and opacities utilizing all the three isotopologues. We find good agreement between temperatures calculated from CO and from dust emission in the dense, energetic regions. We determine the mass and energetics of the clouds, and of the high-velocity material seen in $^{12}$CO emission, and compare the relative energetics of the high- and low-velocity material in the two clouds. We present a CLUMPFIND analysis of the $^{13}$CO condensations. The slope of the condensation mass functions, at the high-mass ends, is similar to the slope of the initial mass function.

Key words: molecular data – stars: formation – ISM: kinematics and dynamics – submillimetre.

1 INTRODUCTION

1.1 The Gould Belt Legacy Survey
The Gould Belt Legacy Survey (GBS; Ward-Thompson et al. 2007) has been awarded 612 h of time on the James Clerk Maxwell...
Telescope (JCMT) to survey nearby star-forming regions (within 500 pc), using Heterodyne Array Receiver Programme (HARP; Buckle et al. 2009), Submillimetre Common-User Bolometer Array 2 (SCUBA-2; Holland et al. 2006) and Polarimeter 2 (POL-2; Bastien, Jenness & Molnar 2005). The HARP component will observe a large typical sample of prestellar and protostellar sources in three CO isotopologues. CO $J = 3 \rightarrow 2$ and the same transition in $^{13}$CO and C$^{18}$O are excited in the physical conditions of star-forming molecular clouds, where typical temperatures and densities are $10–50\ K$ and $10^4–10^5\ \text{cm}^{-3}$. $^{13}$CO observations are used to search for and map any high-velocity outflows present, while the isotopologues measure the linewidths and velocity profiles in the cores and filaments, resolving detailed kinematic and density properties of the cores. The GBS aims to provide a large and unbiased sample of star-forming material in the solar vicinity at relatively high spatial ($8–14\ \text{arcsec}$) and spectral ($0.05–1.0\ \text{km s}^{-1}$) resolution. The GBS will trace the very earliest stages of star formation, through submillimetre continuum imaging using SCUBA-2 observations of low-temperature, high-column density regions, and provide an inventory of all the protostellar objects contained in the nearby molecular clouds of the Gould Belt, covering $\sim 700\ \text{deg}^2$.

The HARP observations trace the kinematics of molecular gas in the cores and clusters at the same spatial resolution as the $850\-\mu\text{m}$ SCUBA-2 observations of the dust emission. The key science goals of the HARP component of the GBS are (Ward-Thompson et al. 2007) as follows:

(i) To search for and map high-velocity outflows in the cores in order to differentiate between starless and protostellar cores.
(ii) To derive simple constraints on the column density and CO depletion in these cores.
(iii) To investigate support mechanisms and cloud.cluster/core evolution.
(iv) To characterize the cloud kinematics in a wide variety of environments and investigate the role and evolution of turbulence in star formation.

The HARP targets for the GBS are a sample of the cloud regions that will be observed by SCUBA-2, with sizes $\sim 0.8\ \text{deg}^2$, and containing filaments and clustered star formation. This paper describes the initial HARP data obtained for two targets in Orion B, NGC 2024 and NGC 2071.

1.2 Orion B

The Orion B cloud complex is the closest region of high-mass star formation, lying at a distance of 415 pc (Anthony-Twarog 1982; Menten et al. 2007). Five main star formation regions were identified from early wide field CO surveys: NGC 2024, NGC 2071, LBS 23 (HH 24), NGC 2068 and NGC 2023 (Tucker, Kutner & Thaddeus 1973; Kutner et al. 1977; White & Phillips 1981; Wilson et al. 2005). The cloud complex subtends an area of $\sim 26\ \text{deg}^2$, which corresponds to $\sim 1.5\ \text{kpc}^2$, and has a mass of $\sim 8 \times 10^4\ \text{M}_\odot$. The main star-forming regions are clearly visible in the unbiased surveys for young stellar objects (Lada, Bally & Stark 1991; Lis, Menten & Zylka 1999; Mitchell et al. 2001; Motte et al. 2001; Johnstone, Matthews & Mitchell 2006, hereafter J06) and in the dense gas tracer CS (Lada et al. 1991). Observations of individual sources in CO lines revealed a complex structure of outflows and gas motions (White, Phillips & Watt 1981; Phillips, White & Ade 1982), which are now known to be associated with extensive star formation activity (Flaherty & Muzerolle 2008). A detailed summary of the Orion B regions can be found in the Handbook of Star Forming Regions (see chapters by Bally 2008; Gibb 2008; Meyer 2008). The two GBS Orion B targets, NGC 2024 and NGC 2071, for which we have obtained the first data are shown as boxes in Fig. 1 overlaid on an extinction map of the Orion B cloud complex.

1.2.1 NGC 2024

NGC 2024 (The Flame Nebula; Anthony-Twarog 1982) is a bright emission nebula that is crossed by a prominent dust lane. Intense radio continuum and recombination line emission (Krügel et al. 1982; Barnes et al. 1989; Bik et al. 2003; Rodríguez, Gómez & Reipurth 2003), plus the detection of an infrared cluster, suggested the presence of ionizing star(s) of spectral type in the range O8–B2 V (Lada et al. 1991; Comerón, Rieke & Rieke 1996; Giannini et al. 2000; Haisch, Lada & Lada 2000; Bik et al. 2003; Kandori et al. 2007).

Millimetre and submillimetre wavelength observations revealed a number of compact condensations that were believed to mark star-forming sites. NGC 2024 has also been shown to contain a number of protostars positioned along a ridge of enhanced star formation activity, and its associated dense molecular material distributed as a filamentary structure (Mezger et al. 1988, 1992; Visser et al. 1998). Far-infrared (FIR) and submillimetre polarimetric observations tracing the magnetic field structure of the star-forming ridge suggest that it contains helical magnetic fields surrounding a curved filamentary cloud, possibly driven by the ionization front of the expanding H ii region (Hildebrand et al. 1995; Dotson et al. 2000; Greaves, Holland & Ward-Thompson 2001; Matthews, Fiege...

& Moriarty-Schieven 2002). Previous molecular line observations of
NGC 2024 have included studies of the outflow and thermal
properties of the gas (Watt et al. 1979; White & Phillips 1981;
Phillips et al. 1988; Barnes et al. 1989; Richer et al. 1989; Barnes
& Crutcher 1990; Richer, Hills & Padman 1992; Chernin 1996;
Mangum, Wootten & Barsony 1999; Snell et al. 2000), revealing a
complex and boisterous medium permeated with outflows, turbulence
and complex gas dynamics.

1.2.2 NGC 2071
NGC 2071 is associated with a reflection nebula, molecular cloud
and infrared cluster NGC 2071IR (Persson et al. 1981; White &
Phillips 1981; White et al. 1981; Johnstone et al. 2001, hereafter
J01; Motte et al. 2001). The main infrared cluster has been resolved
eight into distinct near-infrared sources having a total luminosity
of 520 L⊙ (Butner et al. 1990; Walther et al. 1993). The bipolar
molecular outflow from NGC 2071 has been extensively studied in
CO emission (White & Phillips 1981; Snell et al. 1984; Scoville
et al. 1986; Moriarty-Schieven, Hughes & Snell 1989; Kitamura
et al. 1990; Eisloffel 2000; Houde et al. 2001), and is found to
be amongst the most energetic bipolar outflows currently known,
and extends for ~2 pc (Margulis & Snell 1989; Chemin & Masson
1992; Chemin & Welch 1995; Stojimirovic, Snell & Narayanan
2008). This outflow is also seen in the shock excited 2.12-μm H2
line (Persson et al. 1981; Lane & Bally 1986; Burton, Gehalle
& Brand 1989; Garden, Russell & Burton 1990; Aspin, Sandell
& Walther 1992).

Snell & Bally (1986) have reported the presence of several ex-
tended radio continuum sources. Subsequent observations of H2O
masers and the associated radio continuum emission (Smith & Beck
1994; Torrelles et al. 1998; Seth, Greenhill & Holder 2002) suggest
that the infrared sources IRS 1 and IRS 3 have strong winds and are
surrounded by rotating circumstellar discs. Further outflow activity
around IRS 3 was suggested by its H2 emission (Aspin et al. 1992)
to indicate the presence of a circumstellar disc oriented perpendicular
to the main outflow axis (Walther et al. 1993; Torrelles et al.
1998), that presumably contains a massive protostar.

1.2.3 Outline
In this paper, we present the initial heterodyne data on Orion B
taken for the GBS. We determine characteristic physical properties
for two clouds, NGC 2024 and NGC 2071, comparing and con-
trasting regions with varying physical characteristics. We present
measurements of temperature and opacity across the regions, us-
ing these to provide temperature- and opacity-corrected masses and
energetics of the clouds and the high-velocity material. We use our
13CO data to investigate clumpy structure within the clouds, cal-
culate the mass function of the condensations and compare the
values found with core mass functions in these regions, and to the
initial mass function (IMF). Section 2 provides an overview of the
observations and data reduction. Section 3 describes the reduced
data sets, highlighting regions of interest within the clouds with
reference to previous observations. Section 4 presents the physical
characteristics of opacity, temperature, energetics and kinematics
for the clouds, while Section 5 presents an analysis of the con-
densations as traced by 13CO emission. We summarize the results
presented in the paper in Section 6.

2 OBSERVATIONS

2.1 Overview of HARP
HARP is a recently commissioned spectral-imaging receiver for the
JCMT operating at submillimetre wavelengths (Smith et al. 2003,
2008; Buckle et al. 2009). It works in conjunction with the new back-
end correlator, Auto-Correlation Spectral Imaging System (ACSSIS;
Dent et al. 2000; Buckle et al. 2009) offering high-spectral and spa-
tial resolution, the latter matched to that of SCUBA-2 (Holland et al.
2006). HARP maps spectral lines in the 325–375 GHz atmospheric
window, the JCMT B-band frequencies, where transitions of some
of the most abundant molecules in the interstellar medium reside.
The CO, 13CO and C18O J = 3 → 2 lines in this window are used
by the GBS to trace dense and/or warm gas around star-forming
cores. The HARP imaging array consists of 16 SIS detectors ar-
anged in a 4 × 4 grid, separated by 30 arcsec. The beam size is
14 arcsec at 345 GHz, which means this array arrangement under-
samples the focal plane with respect to Nyquist and further data
points must be taken in between the nominal on-sky positions to
produce a fully sampled map. HARP works in single sideband
mode, with typical receiver noise temperatures under 150 K and
main-beam efficiencies of ηmb = 0.61 (Buckle et al. 2009). The
K-mirror rotates the array with respect to the plane of the sky to
maximize the observing efficiency, for instance allowing large raster
scan maps to be made with the array oriented at an angle to the scan
direction. ACSSIS provides either wide-band (up to 1.9 GHz wide)
or high-resolution spectra (up to 31 kHz channels). Additionally,
the IF can be separated into two sub-bands to allow simultaneous
imaging of two close-together transitions, for example the 13CO and
C18O J = 3 → 2 lines shown here.

2.2 Description of observations
The observations presented here comprise 31.3 h of data taken on
multiple nights from 2007 November to 2008 October. The system
parameters, which are measured for each detector in every ob-
ervation, varied (across different weather bands) from 344 to 684
K for the 12CO and 343 to 575 K for the 13CO/C18O data. Two
fields in Orion B are analysed: (i) NGC 2024, (10.8 × 22.5) arc-
cmin2 centred on 05h41m39.8, −01°54′27″ (J2000) at PA = −40°
(east of north), (ii) NGC 2071, (13.5 × 21.6) arcmin2, centred on
05h47m00s, +00°19′53″ (J2000) angled at PA = −55°. The maps
were taken in the raster position-switched observing mode, where
spectra are taken ‘on-the-fly’ with the telescope constantly scan-
ing in a direction parallel to the sides of the map, taking spectra
separated at 7.3 arcsec along this direction. The array is inclined at
an angle of ~14° to the scan direction which produces rows sepa-
rated by 7.3 arcsec perpendicular to the scan direction automatically
(Buckle et al. 2009). At the end of a scan row, the map is displaced
half the array spacing perpendicular to the scan direction before a
new row is started. This overlaps half of the new scan row’s data
points with the first to double the integration time and even out any
noise variations due to missing receptors or intrinsic differences in
receptor performance. The noise is further evened-out by observing
a second map scanning in a perpendicular direction to the first to
‘basket-weave’ the field.

Separate absolute off positions were used for each field: (1) 05h39m00s, −01°00′00″ for NGC 2024 and (2)
05h43m44s, +00°21′42″ for NGC 2071. Each was verified to be
absent of emission by examining short 60 s position-switched ‘stare’
observations towards each position in 12CO. A low-resolution 12CO

mode (1 GHz bandwidth with 977 MHz channel spacing) was used for this inspection as it provided lower noise and ensured the other weaker isotopologues would also be free of emission.

2.2.1 The GBS HARP/ACSIS configuration

The $^{12}$CO data were taken in an ACSIS dual sub-band mode: (1) with modest resolution to map the broad line flows, at a rest frequency of 345.796 GHz, with the 1 GHz bandwidth divided into 1024 channels, separated by 977 kHz ($\sim$0.85 km s$^{-1}$) and (2), simultaneously, with higher resolution to map the detail of outflows close to the ambient cloud velocity, again at a rest frequency of 345.796 GHz, with 250 MHz bandwidth divided into 4096 channels, separated by 61 kHz ($\sim$0.05 km s$^{-1}$). Similarly, the $^{13}$CO/C$^{18}$O data were taken in a high-resolution dual sub-band mode, each sub-band has a rest frequency of 330.588 or 329.331 GHz, respectively, with the 250 MHz band separated into 4096 61-kHz channels (at a spacing of 0.055 km s$^{-1}$).

2.3 Data reduction

The data were reduced using the STARLINK project software, with KAPPA (Currie et al. 2008) routines used to mask out poorly performing detectors and calculate a self-flat (see Curtis, Richer & Buckle 2009) for each observation. SMURF (Jenness et al. 2008) routines were used to make the cube using a Gaussian gridding technique, with 6 arcsec pixels and a 9 arcsec beam, giving an effective angular resolution of 16.6 arcsec in the final data cubes. KAPPA routines were then used to remove a linear baseline and crop the edges of the cubes spatially and spectrally. These data are presented as a ‘first look’ at the data being gathered for the GBS towards Orion. Data in the isotopically substituted species towards these regions are still being collected, and the final data sets will have a much increased signal-to-noise ratio. Table 1 describes the mean noise achieved in the data cubes collected to date, and the noise requirements of the final GBS data products. Data are presented in units of antenna temperature ($T_A^*$; Kutner & Ulich 1981), which can be converted to main beam temperature ($T_{mb}$) using $T_{mb} = T_A^* / \eta_{mb}$.

3 RESULTS

3.1 HARP spectral imaging

3.1.1 NGC 2024

Fig. 2 displays the total integrated intensity images across the full width of the emission lines towards NGC 2024 in $^{12}$CO 3 $\rightarrow$ 2

$^{1}$ http://starlink.jach.hawaii.edu/starlink

Figure 2. Integrated intensity images of $^{12}$CO (top), $^{13}$CO (middle) and C$^{18}$O (bottom) towards NGC 2024. Crosses mark the positions of sources FIR1–7, and an isolated continuum source to the far south. Contours are $^{12}$CO: from 30 K km s$^{-1}$ with 20 K km s$^{-1}$ steps; $^{13}$CO and C$^{18}$O: from 2 K km s$^{-1}$, with contour levels doubling at every step.

$^{12}$CO: from 30 K km s$^{-1}$ with 20 K km s$^{-1}$ steps; $^{13}$CO and C$^{18}$O: from 2 K km s$^{-1}$, with contour levels doubling at every step.
the cavity in a clumpy ring. The cavity marks a region of bright optical emission. Fig. 3 shows the digitised sky survey (DSS) infrared image overlaid with $^{12}$CO contours. The dense ridge where we see the brightest molecular emission appears as a dark dust lane in the optical image. The bright optical filaments appear in regions which lack $^{12}$CO emission. In particular, the large cavity contoured in $^{12}$CO integrated intensity emission clearly shows the shape of the bright optical emission. The peak of the $^{13}$CO emission is seen in the ridge containing the FIR sources. Further emission follows the $^{12}$CO emission, delineating a cavity surrounded by a ring of clumpy, filamentary structure. The $^{18}$O emission peaks on the positions of the FIR sources in the ridge. Weaker, fragmented and clumpy emission surrounds the cavity seen in $^{12}$CO and $^{13}$CO.

The $^{12}$CO spectra show evidence of several velocity components along the line of sight. Fig. 4 shows the spectra from a single pixel at the peak of $^{18}$O emission, from the three isotopologues. Also shown is a composite spectrum averaged over the observed region. The high-resolution $^{12}$CO spectrum shows four distinct peaks at 4.6 km s$^{-1}$, 8.3 km s$^{-1}$, 11.2 km s$^{-1}$ and 13.0 km s$^{-1}$. The $^{13}$CO spectrum has components at 4.2 km s$^{-1}$, 8.7 km s$^{-1}$ and 11.3 km s$^{-1}$, while the $^{18}$O line has a main component at 11.0 km s$^{-1}$, with a shoulder extension at 9.2 km s$^{-1}$. These line profiles suggest self-absorption in the $^{12}$CO line at 9.6 and 11.9 km s$^{-1}$. Previous observations have also found several velocity components towards NGC 2024 (e.g. Emprechtinger et al. 2009). At 9 km s$^{-1}$, the dense ridge, thought to be in the foreground, is seen as a separate component in $^{18}$O and $^{13}$CO, while there is a dip in the $^{12}$CO spectrum. This supports the suggestion that emission from the blue side of the $^{12}$CO line is being absorbed by foreground material in the dense ridge (Graf et al. 1993; Emprechtinger et al. 2009). The main $^{12}$CO and $^{18}$O components peak near 11 km s$^{-1}$, the velocity of the extended molecular cloud in the background (e.g. Barnes et al. 1989), and we also see a $^{12}$CO component at this velocity. The dip in the $^{12}$CO spectrum at 11.9 km s$^{-1}$, which is part of the main component of the $^{13}$CO and $^{18}$O emission, suggests that there may be a further foreground component at this velocity which is absorbing the $^{12}$CO emission. The self-absorption of the $^{12}$CO emission undoubtedly causes its different peak position to the isotopologues tracing higher column density material. The multiple line-of-sight components are not clearly seen in spectra averaged over the whole region, and demonstrate the importance of high-spectral and spatial resolution observations in understanding the kinematics of star formation/molecular clouds, especially in clustered regions.

Fig. 5 shows position–velocity (PV) diagrams of the three isotopologues across a large section of NGC 2024. The integrated intensity image in the left is marked with two lines showing the right ascension and declination cuts used. In the $^{12}$CO map, we can see a velocity gradient running north–south, from $\sim$13.0 km s$^{-1}$ in the south to $\sim$10.0 km s$^{-1}$ in the north. High-velocity material is seen as extended filaments across much of the PV diagrams, with the brightest high-velocity material seen associated with the ridge in the declination cut. The cavity previously described is labelled in the right ascension cut, at two velocity intervals straddling the main bulk of the molecular cloud at 11.0 km s$^{-1}$. From 12.0 to 14.0 km s$^{-1}$, the cavity shows a distinct velocity gradient along its edge, and is narrower than the outline seen at velocities 8.0–10.0 km s$^{-1}$. The lower-velocity component of the cavity does not

---

Figure 5. PV maps of NGC 2024 in $^{12}$CO, $^{13}$CO and C$^{18}$O, through the positions shown in horizontal and vertical lines in the integrated intensity image on the left.

The PV maps show the velocity gradient along the edge. The very high-velocity outflow material is only clearly seen in the $^{12}$CO PV diagrams, but emission from $^{13}$CO shows extensions in velocity that suggest it is associated with outflow material. Both the $^{12}$CO and $^{13}$CO show compact clumps of emission at blueshifted velocities near 4 km s$^{-1}$, one of the components revealed in the spectra (Fig. 4). The $^{12}$CO PV diagrams show filaments extending between the clumps and the bulk of the emission, suggesting these clumps could be physically associated with the cloud, possibly through wind-driven activity. The emission at redshifted velocities, from 12 to 14 km s$^{-1}$, shows a much smoother distribution than the blueshifted emission. The C$^{18}$O emission is very compact in velocity, tracing the bulk of the dense material in the ridge, and no longer contains the component at 4 km s$^{-1}$.
The GBS Orion Team

Figure 6. Integrated intensity images of $^{12}$CO (top), $^{13}$CO (middle) and C$^{18}$O (bottom) towards NGC 2071. Contours are $^{12}$CO: 30, 35 (white) and 45, 65, 105, 185, 345 (black) K km s$^{-1}$; $^{13}$CO: 7, 9 (white) and 11, 15, 21, 29, 39 (black) K km s$^{-1}$; C$^{18}$O: 2 (white) and 4, 7 (black) K km s$^{-1}$. The first C$^{18}$O contour is at 5σ.

3.1.2 NGC 2071

Fig. 6 shows total integrated intensity images across the full width of the emission lines for $^{12}$CO 3 $\rightarrow$ 2 ($-20.0$ to $35.0$ km s$^{-1}$), $^{13}$CO 3 $\rightarrow$ 2 ($-3.0$ to $18.0$ km s$^{-1}$) and C$^{18}$O 3 $\rightarrow$ 2 ($5.0$ to $12.0$ km s$^{-1}$) towards NGC 2071. The $^{12}$CO emission is dominated by a curved filament of emission, surrounding a compact, bright, optical emission region. Fig. 7 shows the DSS infrared image overlaid with $^{12}$CO contours towards NGC 2071, showing the $^{12}$CO emission nearly surrounding the bright nebula. The $^{13}$CO and C$^{18}$O emission peaks along the compact ridge, but both show a different spatial structure to the $^{12}$CO emission at the southern end of the ridge, at the position of the optical nebula. In $^{13}$CO and C$^{18}$O, the emission to the south, where the $^{12}$CO integrated intensity falls off, displays separate arcs.

The spectra towards individual positions in NGC 2071 are shown in Fig. 8. At the systemic velocity of the cloud, around 10 km s$^{-1}$, the $^{12}$CO is heavily self-absorbed, even in the low-density regions near the optical nebula (Fig. 8, top). Towards the peak of emission from C$^{18}$O (Fig. 8, middle), emission from $^{13}$CO is also self-absorbed. The absorption dip in $^{12}$CO emission is also clear in the spectra averaged across the whole cloud (Fig. 8, bottom).

Fig. 9 shows the PV diagrams for NGC 2071, as for Fig. 5. We see high-velocity material from $^{12}$CO and $^{13}$CO, and evidence for the C$^{18}$O emission tracing lower-velocity outflow material. There is no clear velocity gradient through the cloud. The $^{12}$CO and $^{13}$CO PV diagrams along a cut in right ascension suggest that there may be a second component along the line of sight to the west, or that the cloud is more extended in velocity in this region. In contrast to NGC 2024, towards NGC 2071, we do not see any clear features in the $^{12}$CO PV diagram that may be associated with cavities or bubbles carving out to the cloud edges through activity within the cloud. The C$^{18}$O emission shows a compact, clumpy structure in the PV diagrams.

3.2 High-velocity material

Figs 10 and 11 show false colour red, green and blue images of the average intensity across the $^{12}$CO line profile towards NGC 2024 and NGC 2071, where the emission near the systemic velocity of the clouds is shown in green, and the redshifted and blueshifted gas is shown in the corresponding colour.

Towards NGC 2024, a single region dominates the high-velocity redshifted material, associated with an extended outflow from FIR5 and a compact outflow from FIR6 (Richer et al. 1989). Additionally, more diffuse components are seen throughout the map, which probably indicate different components along the line of sight, rather
NGC 2071 is dominated by a high-velocity outflow, previously identified as one of the most energetic and collimated outflows ever discovered (e.g. Stojimirovic et al. 2008). The false colour image shows there are at least two more outflows, as suggested by Stojimirovic et al. (2008). The PV diagrams (Fig. 9) suggest how powerful this outflow is, with small extensions in velocity showing in the C$^{18}$O emission. Again, the velocity-extended filamentary structures in this large-scale PV diagram suggest that there may be several protostellar outflows embedded within the cloud. In Section 4.5, we investigate the energy injection from outflows in these regions. Fig. 13 shows the blueshifted and redshifted contours overlaid on the C$^{18}$O emission for the main NGC 2071 outflow region, overlaid with SCUBA sources (J06). Redshifted and blueshifted outflow lobes can be identified for at least three and, possibly, five sources.

3.3 Low-density material

Towards both regions, a cavity is seen in emission from $^{12}$CO, associated with an optically bright H II region. However, the behaviour of the less abundant isotopologues, and the velocity structure of these regions, is different towards the two clouds.

Towards NGC 2024, emission from all of the CO isotopologues falls off in this region, as can be seen in the integrated intensity maps (Fig. 2). The cavity is coincident with the bright optical emission, and it may be that we are seeing the CO disassociated by an H II region. Fig. 14 shows the SCUBA 850-μm continuum image (Di Francesco et al. 2008) overlaid with C$^{18}$O integrated intensity contours. The C$^{18}$O emission closely follows the structure seen in the dust, and the clumpiness of both the dust and the C$^{18}$O emission suggests that cores are present in a region surrounding the cavity. We present an analysis of all the $^{13}$CO condensations in Section 5.

In the NGC 2024 $^{12}$CO PV diagram (Fig. 5), the cavity can clearly be seen, and shows a different spatial structure at high and low velocities. There is an abrupt cut-off in emission across the lower velocities, from 8.0 to 10.0 km s$^{-1}$. At the higher velocities, from 12.0 to 14.0 km s$^{-1}$, there is a velocity gradient, and the eastern edge has a higher gradient in velocity than the western edge. If we are seeing an H II region, then the different morphologies between the gas at low velocities and at high velocities may be giving information on the three-dimensional spatial structure. The low velocities, tracing material at the front of the cloud, have an abrupt cut-off to the emission because at this point, the material has broken out of the molecular cloud, and there is no more material entrained in the boundary layers. At higher velocities, tracing material deeper into the cloud, the eastern edge is pushing into the dense molecular ridge seen in the C$^{18}$O emission, while the western edge is pushing into more clumpy and fragmented material. This would account for the different velocity gradients seen in the PV diagrams, and supports the three-dimensional models suggested for this region (Barnes et al. 1989; Emprechtinger et al. 2009).

Fig. 15 shows the NGC 2071 SCUBA 850-μm map (Di Francesco et al. 2008), overlaid with C$^{18}$O integrated intensity contours. The C$^{18}$O emission does not follow the structure seen in the dust as closely as in NGC 2024, and it is in the region co-incident with the optical nebula that we see the most discrepancy. In the PV diagrams (Fig. 9), we see that the $^{13}$CO and C$^{18}$O emission is clumpy and fragmented, both spatially, and in velocity, while the $^{12}$CO emission has a lower intensity region near the systemic cloud velocity, embedded within material at much higher velocities.
Figure 9. PV maps of NGC 2071 in $^{12}\text{CO}$, $^{13}\text{CO}$ and C$^{18}$O, as for Fig. 5.

4 ANALYSIS OF CLOUD PARAMETERS

4.1 Opacity

We calculate the gas opacity based on the line peak ratios of $^{12}\text{CO}/^{13}\text{CO}$ and $^{13}\text{CO}/\text{C}^{18}\text{O}$. The intensity ratio is related to the opacity through

$$ R_{1318} = \frac{T_A^{^{13}\text{CO}}}{T_A^{\text{C}^{18}\text{O}}} = \frac{1 - \exp(-\tau_{13})}{1 - \exp(-\tau_{18})} $$

$$ R_{1213} = \frac{T_A^{^{12}\text{CO}}}{T_A^{^{13}\text{CO}}} = \frac{1 - \exp(-\tau_{12})}{1 - \exp(-\tau_{13})} $$

This method makes several assumptions about emission from the isotopologues (see e.g. Myers, Linke & Benson 1983; Ladd, Fuller & Deane 1998, for details). In particular, the beam efficiency, filling factor and excitation temperature are the same for all the isotopologues, and the ratio of linewidths to the line of sight extent of the emitting gas is the same for all isotopologues.

Where the lines are optically thin, the ratio $R$ should tend to the abundance ratios, $X[^{13}\text{CO}/\text{C}^{18}\text{O}] = 8.4$ and $X[^{12}\text{CO}/^{13}\text{CO}] = 70$ for $^{13}\text{CO}/\text{C}^{18}\text{O}$ and $^{12}\text{CO}/^{13}\text{CO}$, respectively (Frerking, Langer & Wilson 1982; Wilson 1999). The $^{12}\text{CO}/^{13}\text{CO}$ intensity ratio maps for each source are shown in Fig. 16.

From the ratio maps, we can estimate the abundance ratios from the values the ratios tend to towards the edge of detected emission.
regions, where we expect the lines to be optically thin. At the edges of the C\(^{18}\)O emission regions, \(R_{13\text{CO}}\) tends to 8–12 in NGC 2024, and we therefore adopt \(X_{13\text{CO}/C^{18}\text{O}} = 10\) for NGC 2024. For NGC 2071, \(R_{13\text{CO}}\) tends to 6–9, so we similarly adopt \(X_{13\text{CO}/C^{18}\text{O}} = 7.5\). We detect \(12\text{CO}\) and \(13\text{CO}\) across the full extent of the mapped region, and the integrated intensity ratio does not approach the expected abundance ratio of \(\sim 70\). The highest ratios that we detect are \(\sim 20\), suggesting that \(12\text{CO}\) is optically thick in the line core everywhere in both clouds, and so we use \(X_{13\text{CO}/13\text{CO}} = 70\). Using the above equations and abundance ratios, mean opacities in the clouds are \(\bar{\tau}(13\text{CO}) \sim 119\), \(\bar{\tau}(13\text{CO}) \sim 1.7\) and \(\bar{\tau}(C^{18}\text{O}) \sim 0.17\).

### 4.2 Temperature

Assuming local thermodynamic equilibrium (LTE), the excitation temperature \(T_{\text{ex}}\) of the gas can be calculated from line peak rotation.
NGC 2024 generally reaches higher excitation temperatures than NGC 2071. Towards NGC 2024, the mean excitation temperature is 31.8 K, which increases to ≥50 K in the dense regions, and ~70 K in regions which are known to contain energetic outflows. Towards NGC 2071, the mean excitation temperature is 19.6 K, which increases to ≥30 K in the dense regions, and ~50 K in the regions associated with energetic outflows.

Towards the dense cores of Orion B, kinetic temperatures have been published using line ratios of H$_2$CO, a molecule known to trace gas kinetic temperatures extremely well (Mangum & Wooten 1993; Mangum et al. 1999; Tothill & Mitchell 2001). Although only a few of these sources overlap with the regions we have observed, the excitation temperatures calculated from CO agree well with those calculated from H$_2$CO, except towards NGC 2024 FIR5, the probable driving source of the energetic outflow seen as a large redshifted outflow lobe (Fig. 12). Average values for the small number of H$_2$CO dense cores, with the exception of NGC 2024 FIR5, are 44 K from H$_2$CO and 39 K from CO. Given that the H$_2$CO transitions have a critical density of ≥3.9 × 10$^5$ cm$^{-3}$, while the critical density of the $^{12}$CO transition is ~3.5 × 10$^4$ cm$^{-3}$, and that the velocity structure of these regions is relatively complex, this is surprising, and suggests the combination of $^{12}$CO and $^{13}$CO is a relatively good tracer of excitation conditions in dense regions. We have also compared our CO excitation temperatures with those derived from dust temperatures towards SCUBA cores in both clouds by J01 and J06. Fig. 18 shows the integrated intensity maps of $^{12}$CO, overlaid with contours of C$^{18}$O, and marked with the positions of the SCUBA dust cores from J01 and J06. The cores are marked in green if $T_{\text{ex}}$(CO) (Section 4.1). Following Garden et al. (1991), the ratio is >1.5, and in red if the ratio is >1.5. For the small number of cores that also have H$_2$CO measurements, the average dust temperature is 41 K, similar to the H$_2$CO and CO values. Towards NGC 2071, all of the SCUBA cores have CO and dust temperatures ratios ≤1.5, while towards NGC 2024, the ratio is ≤1.5 only towards the high column density regions of NGC 2024, along the molecular ridge. Towards NGC 2024, the cores where dust temperatures are similar to temperatures derived from CO are spatially grouped towards the highest column density regions. In NGC 2024, the differences in $T_{\text{ex}}$(CO) and $T_{\text{dust}}$ towards the lower column density regions may be evidence of subthermal excitation of CO. Given the complex velocity structure of these regions, and the complications that opacity adds to the line profile, observations utilizing all CO isotopologues so that opacity corrections can be made appear to be relatively good tracers of the gas and dust temperatures in energetic, densely clustered regions.

4.3 Mass and energetics

Since we have isotopic data, we can calculate the mass in the large-scale cloud, using the $^{12}$CO and $^{13}$CO data, which we detect everywhere. In the dense molecular ridge, where $^{12}$CO and $^{13}$CO line profiles are affected by self-absorption, we can use the C$^{18}$O data, assuming LTE conditions. We compute the masses assuming $T_{\text{ex}}$ is the same for all three isotopologues, and equal to the mean $^{12}$CO excitation temperature (Section 4.2). We correct for optical depth effects in the $^{12}$CO and $^{13}$CO data using the mean opacities $\bar{\tau}$($^{13}$CO) and $\bar{\tau}$($^{12}$CO) (Section 4.1). Following Garden et al. (1991),

$$N(\text{C}^{18}\text{O}) = 8.26 \times 10^{13} \exp\left(\frac{15.81}{T_{\text{ex}}}\right) \times \frac{T_{\text{ex}} + 0.88}{1 - \exp(-15.81/T_{\text{ex}})} \int \tau \, dv \, cm^{-2},$$

$$\int \tau \, dv \, cm^{-2}.$$
The $^{12}$CO/$^{13}$CO (left) and $^{13}$CO/C$^{18}$O (right) peak intensity ratios for regions with detections <3σ towards NGC 2024 (top) and NGC 2071 (bottom), overlaid with C$^{18}$O integrated intensity contours. The $^{13}$CO/C$^{18}$O ratio data has been smoothed by a Gaussian with 12 arcsec full width at half-maximum (FWHM) to make the features more visible in these images.

$N(^{13}$CO) = 8.28 \times 10^{13} \exp \left( \frac{15.87}{T_{ex}} \right) \times \frac{T_{ex} + 0.88}{1 - \exp \left( -\frac{15.87}{T_{ex}} \right)} \int \tau \, dv \, \text{cm}^{-2} \, \text{and}$

$N(^{12}$CO) = 7.96 \times 10^{13} \exp \left( \frac{16.6}{T_{ex}} \right) \times \frac{T_{ex} + 0.92}{1 - \exp \left( -\frac{16.6}{T_{ex}} \right)} \int \tau \, dv \, \text{cm}^{-2},$  

where we use the approximations

$\int \tau \, dv = \frac{1}{[J(T_{ex}) - J(T_{BG})]} \int T_{mb} \, dv \, \text{for} \, \tau \geq 1$  

$\int \tau \, dv = \frac{1}{[J(T_{ex}) - J(T_{BG})]} \int T_{mb} \, dv \, \text{for} \, \tau \ll 1$  

$J(T) = \frac{T_{ex}}{\exp \left( \frac{T_{ex}}{T_0} \right) - 1}$  

$T_0 = \frac{h \nu}{k},$  

with $T_{BG} = 2.7$ K. The mass is given by

$M_{\text{gas}} = 1.13 \times 10^{-4} \mu_{\text{He}} m_d^2 \Delta \alpha \Delta \beta X N(CO) M_\odot$  

where $\Delta \alpha \Delta \beta$ is the pixel area in arcsec$^2$, $d$ is the distance in pc, $v$ is in km s$^{-1}$ and $X$ is the isotopic abundance ratio of CO and its isotopologues relative to H$_2$. We adopt a mean molecular weight per H$_2$ molecule of $\mu_{\text{He}} = 2.72$ to include helium, and $X[^{12}\text{CO}] = 1.0 \times 10^{-4}$, $X[^{13}\text{CO}] = 1.4 \times 10^{-6}$, $X[\text{C}^{18}\text{O}] = 1.7 \times 10^{-7}$ (Frerking et al. 1982; Wilson 1999). The results are listed in Table 2. The masses that we find for optically thick $^{12}$CO are smaller than previous mapping observations of a 19 deg$^2$ region in Orion B, using a lower excitation transition, where a total mass of $8.3 \times 10^4 M_\odot$ was measured (Maddalena et al. 1986). The total mass we derive for NGC 2024 and NGC 2071, covering a region ~100 times smaller in area and using optically thick $^{12}$CO, is $8.5 \times 10^3 M_\odot$. In $^{13}$CO, we find a total mass of $2.5 \times 10^3 M_\odot$. The total mass of gas that we detect in C$^{18}$O towards both clouds is $1000 M_\odot$. Emission from the optically thin isotopologue C$^{18}$O traces a smaller region within the cloud, and does not suffer from the same uncertainties due to optical depth corrections. If the opacity corrections using mean values were accurate, we would perhaps expect the masses calculated from $^{12}$CO and $^{13}$CO emission to be similar to that calculated from...

Figure 16. The $^{12}$CO/$^{13}$CO (left) and $^{13}$CO/C$^{18}$O (right) peak intensity ratios for regions with detections <3σ towards NGC 2024 (top) and NGC 2071 (bottom), overlaid with C$^{18}$O integrated intensity contours. The $^{13}$CO/C$^{18}$O ratio data has been smoothed by a Gaussian with 12 arcsec full width at half-maximum (FWHM) to make the features more visible in these images.
C\textsuperscript{18}O emission. However, the differences may be due to physical conditions within the clouds affecting the transitions differently. Towards NGC 2024 in particular, the many velocity components seen in the spectra indicate that a single excitation temperature and density along the line of sight may not be a good approximation of the conditions. The clouds may not be in LTE, and emission from the isotopologues subthermally excited. As suggested by Pineda et al. (2008), the shielding of material within the cloud leads to physical and chemical properties which can affect \textsuperscript{12}CO and \textsuperscript{13}CO differently to the rarer isotopologue C\textsuperscript{18}O. We find a total mass of 1111 M\textsubscript{☉} using \textsuperscript{13}CO data, if we assume that \textsuperscript{13}CO emission is also optically thin. The total mass calculated from \textsuperscript{12}CO under the assumption of optically thin emission is 65 M\textsubscript{☉}, indicating that emission from this isotopologue is, as calculated above, very optically thick, and tracing only the surface regions of the clouds. NGC 2024 contains more mass than NGC 2071, measured in all of the isotopologues.

The gravitational potential energy, $W$, of the cloud can be calculated assuming a density distribution $\rho \propto r^{-d}$ (MacLaren, Richardson & Wolfendale 1988; Bertoldi & McKee 1992; Williams, de Geus & Blitz 1994). The kinetic energy, $E_{\text{kin}}$, can be calculated by estimating the three-dimensional velocity dispersion, $\sigma_{\text{v,3D}}$, from the one-dimensional velocity dispersion of the average spectrum, $\sigma_{\text{v,1D}}$, or $\sigma_{\text{v,3D}}$:

$$W = -\frac{3}{5} \frac{GM_{\text{gas}}^2}{R}$$

(12)

Table 2. Table of masses and energetics.

| Cloud     | \textsuperscript{12}CO (×10\textsuperscript{3} M\textsubscript{☉}) | \textsuperscript{13}CO (×10\textsuperscript{3} M\textsubscript{☉}) | C\textsuperscript{18}O (×10\textsuperscript{3} M\textsubscript{☉}) | \textsuperscript{12}CO (×10\textsuperscript{20} J) | \textsuperscript{13}CO (×10\textsuperscript{20} J) | C\textsuperscript{18}O (×10\textsuperscript{20} J) |
|-----------|-----------------------------|-----------------------------|-----------------------------|-----------------------------|-----------------------------|-----------------------------|
| NGC 2024  | 4.8                         | 1.6                         | 0.6                         | 37.5                       | 5.9                        | 1.6                         |
| NGC 2071  | 3.7                         | 0.9                         | 0.4                         | 24.5                       | 1.6                        | 0.4                         |
|           |                             |                             |                             | 5.7                         | 1.1                        | 0.2                         |

Figure 17. Excitation temperature (in K) for NGC 2024 (top) and NGC 2071 (bottom). To indicate regions where the \textsuperscript{12}CO may be self-absorbed, and so underestimating the excitation temperature, the contours show C\textsuperscript{18}O integrated intensity.

Figure 18. \textsuperscript{12}CO integrated intensity maps for NGC 2024 (top) and NGC 2071 (bottom), overlaid with C\textsuperscript{18}O contours. SCUBA cores from J01 and J06 are marked in green where the ratio $T_{\text{ex}}$\textsuperscript{(12)CO}/$T_{\text{dust}}$ ≤ 1.5 and in red otherwise.
\[
\gamma = \frac{1 + \alpha/3}{1 + 2\alpha/5}
\]  

(13)

\[
E_{\text{kin}} = \frac{1}{2} M_\text{gal} v^2
\]  

(14)

\[
v^2 = \sigma_{\text{3D}}^2 = 3 \left[ \sigma_{\text{CO}}^2 + \frac{kT}{m_\text{H}} \left( \frac{1}{\mu} - \frac{1}{m_{\text{CO}}} \right) \right].
\]  

(15)

where \( G \) is the gravitational constant, \( k \) is Boltzmann’s constant, \( T \) is the kinetic temperature of the gas, which we have taken to be equal to the mean \(^{12}\text{CO} \) excitation temperature and \( m_{\text{CO}} \) is the atomic mass of \(^{12}\text{CO}, \(^{13}\text{CO} \) or \(^{18}\text{O} \). We assume the clouds follow \( \rho \propto r^{-2} \) density distributions, yielding \( \gamma = 5/3 \). The LTE masses, kinetic and gravitational potential energies of both clouds are listed in Table 2.

NGC 2024, as well as containing more mass than NGC 2071, has greater kinetic and gravitational potential energies. The gravitational potential energy calculated from \(^{12}\text{CO} \) and \(^{13}\text{CO} \) is larger than the kinetic energy in both regions, implying that these clouds are both gravitationally bound. The emission from \(^{18}\text{O} \), tracing much smaller regions containing all of the currently active outflows, has more kinetic energy. The line profiles and PV diagrams of \(^{12}\text{CO} \) and \(^{13}\text{CO} \) indicate that both of these isotopologues are tracing some of the high-velocity, presumably outflowing, material. In Section 4.5, we compare these values to the energetics in the high-velocity material.

### 4.4 Cloud kinematics

Fig. 19 shows the velocity at the line peak of the optically thin gas. This has been created from the \(^{13}\text{CO} \) and \(^{18}\text{O} \) data, using \(^{13}\text{CO} \) in regions where the \(^{18}\text{O} \) line peak falls below the 3σ level. Towards NGC 2024, a velocity gradient runs across the image, from 8 km s\(^{-1} \) in the north, to 10 km s\(^{-1} \) in the south, with the molecular ridge in the south seen in emission at 11.5 km s\(^{-1} \). The dust cavity is seen in material at \( \geq 11.5 \) km s\(^{-1} \), surrounded by material at 8.0–10.0 km s\(^{-1} \), with a further higher velocity band to the northwest. In the southernmost part of the map, a band of high-velocity material appears, which is the tip of the NGC 2023 region. The velocity gradient can also be clearly seen in the \(^{12}\text{CO} \) PV diagram (Fig. 5). Towards NGC 2071, there is no obvious underlying velocity gradient. All of the velocity variations seen in the NGC 2071 map appear to be associated with current star-forming activity in the cloud. In the south, there is a large region that is clearly redshifted with respect to the rest of the cloud, which is in the same direction as the very energetic redshifted outflow lobes seen towards NGC 2071 (Fig. 13).

Fig. 20 shows the equivalent width (\( \int T\nu \, d\nu/\nu_{\text{peak}} \)) for the optically thin emission towards the two regions. The exterior edges of the molecular ridge towards NGC 2024, traced by the outer contours of \(^{18}\text{O} \), have lower-velocity dispersions than the material within which it is embedded, and the energetic region near the FIR sources. Towards NGC 2071, the material with a lower-velocity dispersion is perpendicular to the outflow direction. In the regions extending along the outflow, a cone-shape of higher velocity dispersion material can be seen.

### 4.5 Mass and energetics of the high-velocity material

Using the line centre of the average \(^{18}\text{O} \) spectrum to identify the velocity of the cloud, we calculate the total mass in the high-velocity material generated from the outflows using \(^{12}\text{CO} \) emission, with red- and blue-velocity extents across the line profile. We assume that the high-velocity emission is optically thin, and at a similar excitation temperature to the bulk of the gas, given by the mean \(^{12}\text{CO} \) excitation temperature, following the method in Section 4.3. We obtain masses of a few times \( 1 \) M\(_\odot \). This is much lower than found using lower excitation transitions of \(^{12}\text{CO} \) and \(^{13}\text{CO} \) (e.g. Snell et al. 1984; Stojimirovic et al. 2008, although these authors used a combination of isotopologues across the velocity range for their calculation).

For \(^{13}\text{CO} \), where the assumption that the emission is optically thin in the line wings is more likely to be correct, we obtain masses approximately a few times \( 10 \) M\(_\odot \), in better agreement with those previously found, which suggests the optically thin assumption for \(^{12}\text{CO} \) line wings produced in outflows is not valid.

From the \(^{13}\text{CO} \) emission, we calculate the energy and momentum of this high-velocity material using

\[
P = MV_{\text{char}}
\]  

(16)

\[
E_k = \frac{1}{2} MV_{\text{char}}^2,
\]  

(17)

where \( V_{\text{char}} \) is a characteristic velocity estimated as the difference between the maximum velocity with detectable emission in \(^{12}\text{CO} \) emission and the cloud velocity identified from the line centre velocity of a Gaussian fit to the average \(^{18}\text{O} \) line profile. For
energy in NGC 2024, while the high-velocity material dominates the kinetic energy in NGC 2071.

### 5 Analysis of the gaseous condensations

The structure of molecular clouds has been characterized in numerous ways in the literature, including identifying discrete objects in the emission (often termed clumps). By studying the properties of such clumps we hope to explore the properties of the cores, harboured by some of the clumps, which will go on to form stars. Frequently, automated clump-finding routines have been used, to look for clumps in an unbiased manner, in both spectral-line and dust continuum data sets. In this section, we undertake a statistical decomposition of the structure of the $^{13}$CO $J = 3 \rightarrow 2$ emission using the clumpfind algorithm (Williams et al. 1994), implemented in Starlink’s new Cupid package (Berry et al. 2007). The optically thin $^{13}$CO $J = 3 \rightarrow 2$ data will be a better tracer of the mass in the star-forming cores, where the $^{13}$CO line is saturated. Here, we explore the $^{13}$CO $J = 3 \rightarrow 2$ bulk cloud emission. Many different terminologies have been used to name clumps in molecular clouds; here we call any individual object identified using clumpfind a ‘condensation’, to emphasize that it may not collapse to form a star.

The data were smoothed to 0.25 km s$^{-1}$ spectrally to improve the signal-to-noise ratio but still maintain sufficient resolution to identify condensations with the narrowest anticipated linewidths. At our assumed cloud temperatures (50 and 30 K for NGC 2024 and NGC 2071, respectively), the $^{13}$CO linewidths expected from thermal broadening alone ($\sqrt{KT/m_{m(CO)}}$) are 0.4 km s$^{-1}$ for NGC 2024 and 0.3 km s$^{-1}$ for NGC 2071. At this resolution, the mean rms noise across the map is reduced to 0.14 and 0.20 K for NGC 2024 and NGC 2071, respectively. We ran clumpfind using a level spacing of 2 $\sigma_{rms}$ [the value recommended by Williams et al. (1994) to reduce the contamination by noise] and a lowest level of 2 $\sigma_{rms}$, which ensures that the minimum peak intensity of a condensation is 4 $\sigma_{rms}$. Additionally, condensations were rejected if they touched any edge of the data array, contained fewer than 16 (3D) pixels or were smaller than the beam size. These parameters resulted in a catalogue of 1561 and 1399 condensations in NGC 2024 and NGC 2071, respectively.

Previous studies of the clump distribution in the dust continuum emission of Orion B have identified a factor of ~10 fewer condensations than we do from the $^{13}$CO emission (J01, J06). This is probably because the SCUBA observations are not sensitive to flux on large scales whereas the $^{13}$CO gas should trace this more ambient emission, which can account for the $^{13}$CO condensations identified which are not spatially associated with a dust clump. Additionally, the spectral information in the $^{13}$CO data may break up multiple condensations at distinct velocities along the line of sight, which may be superposed in continuum data. For each dust clump identified by J01 and J06 in our observing fields, we found the mean

[by guest on 25 July 2018]
number of $^{13}$CO condensations whose peak lies within the radii of the dust clumps to be $\sim$7.4 for NGC 2024 and $\sim$3.7 for NGC 2071.

5.1 Condensation properties

In the catalogue generated by CUPID, the ‘size’ of each condensation along each axis (right ascension, declination and velocity) is given by the standard deviation of the pixel co-ordinate values about the centroid position, weighted by the pixel values, then corrected to remove the effect of instrumental smoothing. We define the radius of a condensation as the geometric mean of the size along axes 1 and 2 ($R_1$ and $R_2$):

$$R = \sqrt{R_1 R_2},$$

(18)

where $R_1$ and $R_2$ have already been deconvolved with the beam size.

For NGC 2024, the condensation radii range from $1.3 \times 10^{-3}$ to 0.053 pc with a mean value of 0.018 $\pm$ 0.009 pc. For NGC 2071, the values are similar; the radii range from $1.3 \times 10^{-3}$ to 0.075 pc with a mean value of 0.017 $\pm$ 0.008 pc.

We estimate the three-dimensional velocity dispersion of each condensation from the one-dimensional $^{13}$CO velocity dispersion, $\sigma_{^{13}CO}$ (the size along axis 3 calculated by CUPID), as described in Section 4.3. For NGC 2024, the velocity dispersions range from 0.66 to 2.0 km s$^{-1}$, with a mean value of 0.99 $\pm$ 0.23 km s$^{-1}$. Again, the values are similar for NGC 2071, ranging from 0.50 to 2.5 km s$^{-1}$ with a mean of 0.88 $\pm$ 0.19 km s$^{-1}$.

Assuming the clouds are in LTE and the $^{13}$CO $J = 3 \rightarrow 2$ transition is optically thin, the masses of the $^{13}$CO clumps can be derived following Section 4.3. At moderately high densities (which we expect the $^{13}$CO $J = 3 \rightarrow 2$ transition to probe, given its critical density), the cloud gas and dust should be coupled and at the same temperature (Burke & Hollenbach 1983). The mean temperatures of the dust clumps associated with our $^{13}$CO condensations, computed by J06 and J01, are 45 $\pm$ 11 K and 26 $\pm$ 8 K for NGC 2024 and NGC 2071, respectively. We therefore adopt excitations temperatures of $T_{ex} = 50$ and 30 K for NGC 2024 and NGC 2071, respectively, in our mass calculations, which are also consistent with the temperatures we derived in Section 4.2 (see Fig. 17).

In NGC 2024, we find the masses of the condensations range from $2.6 \times 10^{-3}$ to 13 $M_\odot$, with a mean value of 0.52 $\pm$ 1.2 $M_\odot$. For NGC 2071, the condensations are less massive, ranging from $3.4 \times 10^{-3}$ to 5.3 $M_\odot$, with a mean value of 0.22 $\pm$ 0.34 $M_\odot$. These masses are much less than those derived from the dust analysis of J06 and J01, who found clumps as massive as 90 $M_\odot$ in NGC 2024 and 30 $M_\odot$ in NGC 2071. As mentioned above, this could be because there are several $^{13}$CO condensations associated with each dust clump. Furthermore, opacity effects and freeze-out of CO in dense regions could reduce the observed intensity and hence the mass estimate.

The virial mass of a spherical condensation with a density profile of $\rho \propto r^{-\gamma}$ is calculated using (MacLaren et al. 1988; Williams et al. 1994)

$$M_{vir} = \frac{5 R^2 \sigma_{^{13}CO}^2}{3 \gamma G},$$

(19)

where $R$ is the radius of the condensation, $\sigma_{^{13}CO}$ is the three-dimensional velocity dispersion (equation 15) and $G$ is the gravitational constant. Assuming the condensations have density distributions of $\rho \propto r^{-2}$, $\gamma = 5/3$. The virial masses for NGC 2024 range from 0.21 to 30 $M_\odot$ with a mean of 5.1 $\pm$ 4.6 $M_\odot$, while for NGC 2071 $M_{vir}$ ranges from 0.13 to 32 $M_\odot$ with a mean, 3.4 $\pm$ 2.7 $M_\odot$. The virial masses are much higher than the LTE masses for every condensation, but this is partly because the LTE masses are underestimates.

5.2 Correlation between the condensation properties

In Fig. 21, we plot the $M_{LTE} - R$ and $\sigma_v - R$ relations for both clouds. In the plots of $M_{LTE}$ versus $R$, there appears to be a separate population of low-mass condensations. These low-mass condensations are roughly separated by the line $M_{LTE}/M_\odot = R$/pc and are plotted in red. The remaining condensations (plotted in black) appear to have a strong correlation between mass and radius, with correlation coefficients of 0.8 for both clouds. The linear regression coefficient ($s_1/s_2$) of log($M_{LTE}/M_\odot$) versus log($R$/pc) is 2.6 for NGC 2024 and 1.7 for NGC 2071, implying that the mass–radius relationship is of the form $M_{LTE}/M_\odot \propto (R/$pc$)^{-2.6}$ and $\propto (R/$pc$)^{-1.7}$ for NGC 2024 and NGC 2071, respectively. Given the scatter in the plots and the uncertainties in the values of $M_{LTE}$ and $R$, the relation for both clouds is consistent with the one found by Kramer, Stutzki & Winnewisser (1996) for their $^{13}$CO condensations in the southern part of Orion B, which had a power-law index of 2.2. The relations are also consistent with Larson’s law relating mass and radius, which is of the form $M_{LTE} \propto R^2$ (Larson 1981). In Fig. 21, the linear regression fits are shown with the solid black line, and the Larson relation is shown with the broken line.

The distinct population of low-mass condensations, on the other hand, only has a weak correlation between mass and radius (with correlation coefficients of 0.5 in both clouds). Since these populations have such low masses and behave differently to the rest of the condensations, it is possible that they have some contamination from noise or they may be a population of transient objects in the ambient cloud, not related to the active star formation.

Figure 21. $M_{LTE} - R$ (top panels) and $\sigma_v - R$ (bottom panels) relations for NGC 2024 (left) and NGC 2071 (right). Condensations with $M_{LTE}/M_\odot < R/$pc are plotted in red because they appear to form a separate population. In the top panels, the dotted lines show $M_{LTE}/M_\odot = R$/pc; the dashed lines show $M_{LTE} \propto R^2$ (Larson’s Law) and the solid lines show the lines of the best fit: $M_{LTE} \propto R^{2.6}$ for NGC 2024 and $\propto R^{1.7}$ for NGC 2071.
The GBS Orion Team

α = 0.12. Fitting a double power law gives M \sim 10^204–222 for NGC 2024 and M \sim 10^1.000 for ratios). Below this M for NGC 2071). The dotted line on each plot shows where the condensations are in approximate equipartition (£M_{\text{vir}} / M_{\odot} < 2 M_{\odot}$), which has been interpreted as evidence over a large range of environments. For instance, the similarity of the CMF to the IMF for the earliest stages of protostellar evolution may rule out models of star formation where the shape of the CMF is set at later stages (e.g. Bate & Bonnell 2005).

Fig. 23 compares the plots of dN/dM versus M_{\text{LTE}} for both clouds. The crosses mark the mass function including all of the condensations and the diamonds mark the mass function with the population of low-mass condensations, discussed in Section 5.2, removed. The errors plotted show the statistical uncertainties of \sqrt{N}, where N is the sample number in each mass bin. The two mass functions for each cloud are the same for M_{\text{LTE}} \approx 0.02 M_{\odot}. Below this mass, the total mass function continues to increase with decreasing mass, whereas the mass function with the low-mass population removed has a turning point and begins to decrease with decreasing mass. Due to the increasing incompleteness in the mass function at these low masses arising from our detection thresholds, we have only attempted to fit the mass function for M_{\text{LTE}} \approx 0.02 M_{\odot}.

Reduced-squared fitting of a single power-law mass function to NGC 2024 gives \alpha \sim 1.3 for M_{\text{LTE}} \approx 0.02 M_{\odot} (plotted with the dashed line on Fig. 23). The data suggest that there is a break in the power law at M_{\text{LTE}} \approx 2.0 M_{\odot}. Fitting a double power law gives \alpha_{\text{low}} \sim 1.0 for 0.02 < M_{\text{LTE}} / M_{\odot} < 2.0 and \alpha_{\text{high}} \sim 2.6 for M_{\text{LTE}} > 2 M_{\odot}.

For NGC 2071, a single power law gives \alpha \sim 1.7 for M_{\text{LTE}} \approx 0.02 M_{\odot}, but it is clear that the mass function flattens off for 0.02 < M_{\text{LTE}} / M_{\odot} < 0.12. Fitting a double power law gives \alpha_{\text{low}} \sim 0.06 for 0.02 < M_{\text{LTE}} / M_{\odot} < 0.12 and \alpha_{\text{high}} \sim 2.3 for M_{\text{LTE}} > 2 M_{\odot}. The data suggest there could be another break in the power law at M_{\text{LTE}} \approx 1.0 M_{\odot}.

The single power-law values for \alpha are similar to the values of 1.6–1.8 derived using isotopologues of CO by Kramer et al. (1998) for seven molecular clouds, including Orion B South. For the double power-law fits, the values of \alpha_{\text{low}} are similar to those derived by J01 for the dust condensation of Orion B North and by Ikeda et al. (2009) for the H13CO+ condensations of Orion B, which had values ranging from 2.3 to 3.0. These values are also very similar to the slope of the IMF (\alpha = 2.35), which has been interpreted as evidence for a physical link between the CMF and IMF.

Figure 22. Plots of virial mass versus LTE mass for NGC 2024 (left) and NGC 2071 (right). Condensations with M_{\text{LTE}} / M_{\odot} < 2 \text{pc} are plotted in red. The solid lines on each plot show the best fit (M_{\text{vir}} \propto M_{\text{LTE}}^0.4 for NGC 2024 and M_{\text{LTE}}^0.6 for NGC 2071) and the dotted lines show M_{\text{vir}} = M_{\text{LTE}}.

The plots of the velocity dispersion against radius in Fig. 21 do not show an obvious correlation. This is reflected in the low values of the correlation coefficients (0.2 for each cloud). In these plots, the populations of low-mass condensations mentioned above are also plotted in red, but here they are not distinct from the other condensations. Several other surveys have also found very weak or no correlation between \sigma_v and R for condensations in molecular clouds (e.g. Kramer et al. 1996; Onishi et al. 2002). For a larger range of molecular cloud sizes, Larson (1981) found that \sigma_v \propto R^{-0.4}. The lack of correlation found here could be because of the small range in R and \sigma_v, and the large scatter in the values.

Fig. 22 shows the relationship between M_{\text{vir}} and M_{\text{LTE}}. Again, the low-mass condensations identified above are plotted in red, and they appear as a distinct population in this plot. The rest of the condensations are relatively well correlated, with correlation coefficients of 0.9 for NGC 2024 and 0.8 for NGC 2071. The plots appear to be well-fitted with a power law (solid line), M_{\text{vir}} \propto M_{\text{LTE}}^0.4 for NGC 2042 and 0.6 for NGC 2071, calculated from the regression coefficient in log–log space. Ikeda, Kitamura & Sunada (2009) found \alpha_{\text{LTE}} / M_{\text{LTE}}^0.55 for H13CO+ condensations in Orion B (i.e. \beta = 0.67), which is very close to our value for NGC 2071. The dotted line on each plot shows where the condensations are in approximate equipartition (M_{\text{vir}} = M_{\text{LTE}}). The condensation virial masses are in fact much higher than their LTE masses, implying that the condensations are unbound. However, there are large uncertainties in both the virial and LTE masses (because of, for example, uncertainties in the distances to the cloud, the fractional abundance of 12CO, the excitation temperature and the assumed density profile); therefore we cannot make any definite conclusions about the fate of any particular condensation from this plot. However, the relative positions of the condensations to each other should be more robust and suggests that condensations from the low-mass population (in red) are in general less bound than the rest (i.e. they have higher M_{\text{vir}} / M_{\text{LTE}} ratios).

5.3 Condensation mass function

The differential condensation (or core) mass function (CMF) is usually fitted by the power law

\frac{dN}{dM} \propto M^{-\alpha}.

(20)

If these condensations are the direct precursors of stars, the form of the CMF may provide insights into the origin of the stellar IMF, which is described by equation (20) with \alpha = 2.35 (Salpeter 1955)

\frac{dN}{dM} \propto M^{-\alpha}.

(20)

If these condensations are the direct precursors of stars, the form of the CMF may provide insights into the origin of the stellar IMF, which is described by equation (20) with \alpha = 2.35 (Salpeter 1955)
Ikeda et al. (2009) also found $\alpha_{\text{low}} \sim 0.06$, just as we have found for NGC 2071. They suggested the flattening could be a confusion effect where low-mass cores are misidentified as parts of high-mass cores. The turnover point found by Ikeda et al. (2009) was much higher, however, at $6 M_\odot$, compared to our value of 0.12 $M_\odot$. Again, this could be because the $^{13}$CO LTE masses are underestimated due to opacity and freeze-out.

From our analysis on the $^{13}$CO condensations in NGC 2024 and NGC 2071, we have found that NGC 2024 has a wider mass range than NGC 2071 (with masses up to $\sim 13 M_\odot$ for NGC 2024, compared to $\sim 5 M_\odot$ for NGC 2071). Compared to the virial masses and condensation masses derived from other tracers, the $^{13}$CO mass estimates appear to be underestimated, possibly due to optical depth and freeze-out effects. The relationships between the condensation properties are similar to those seen in previous surveys of condensations of CO isotopologues and H$^{13}$CO$^+$. The slopes of the CMF at the high-mass ends ($\sim 2.6$ for NGC 2024 and $\sim 2.3$ for NGC 2071) are very similar to the slope of the IMF.

6 SUMMARY

We have offered a first look at the data on Orion B being collected by HARP/ACISIS on the JCMT for the GBS. Our observations of CO, $^{13}$CO and C$^{18}$O $J = 3 \rightarrow 2$ provide a comprehensive determination of the characteristic physical properties and dynamics of star-forming regions. We have observed two large regions in Orion B, (10.8 $\times$ 22.5) arcmin$^2$ in NGC 2024 and (13.5 $\times$ 21.6) arcmin$^2$ in NGC 2071. Towards NGC 2024, $^{12}$CO and $^{13}$CO are detected throughout the region, while C$^{18}$O is detected in an extended ridge, which follows the dust emission, and also in a fragmented ring surrounding a bright optical nebula. The $^{13}$CO line profiles indicate multiple line-of-sight components. Comparisons of the intensity ratios of the three isotopologues indicate that the $^{12}$CO is optically thick throughout the cloud, and also in the lower-velocity outflow material, while the C$^{18}$O is generally optically thin. These opacity results also apply to NGC 2071.

Towards NGC 2071, the molecular gas is concentrated in a region almost completely surrounding a bright optical nebula. The $^{12}$CO emission is heavily self-absorbed, and $^{13}$CO also shows self-absorption in the densest regions. The main outflow is very energetic, and is seen to produce extended wings even in the C$^{18}$O line profiles.

Both clouds show a complex clumpy and filamentary structure. In the regions traced by C$^{18}$O, the equivalent widths suggest the bulk of the quiescent material has a lower-velocity dispersion than the material in which it is embedded, increasing only in the regions of current star formation. The energetic outflow activity is contributing a few per cent of the kinetic energy of NGC 2024, while the outflows dominate the kinetic energy towards NGC 2071. Towards NGC 2024, the low-velocity redshifted material is extended and filamentary, while the low-velocity blueshifted material is clumpy and compact.

A CLUMPFIND analysis on the $^{13}$CO data finds multiple $^{13}$CO condensations spatially associated with SCUBA dust cores, $\sim 7.4$ towards NGC 2024 and $\sim 3.7$ towards NGC 2071. The condensations in NGC 2024 have higher LTE and virial masses than in NGC 2071, and towards both clouds, $M_{\text{vir}} \geq M_{\text{LTE}}$. The slopes of the CMF at the high-mass ends are in agreement with the slope of the IMF. Towards NGC 2024, we also detect a group of condensations that appear to be less bound, which may be tracing transient clumps that do not go on to form stars.

These data are still being collected, and the GBS has a final 1$\sigma$ noise requirement of 0.3 K in 1.0 km s$^{-1}$ for $^{12}$CO and 0.3 K in 0.1 km s$^{-1}$ for C$^{18}$O per 7.5 arcsec pixel. $^{13}$CO is obtained simultaneously with C$^{18}$O, and the C$^{18}$O requirement sets a 1$\sigma$ noise level of 0.25 K in 0.1 km s$^{-1}$ for $^{13}$CO. When the full HARP data set has been obtained, we will carry out more detailed analyses of the individual cores and outflow properties in the Orion B clouds. The completeness limit for the $^{13}$CO results will be improved, although overall condensation masses and the slope of the CMF will not be significantly affected. With data sets of the same sensitivity, the properties of the Orion B clouds will be compared to the other star-forming clouds being observed by the GBS. This data set will be highly complementary to the SCUBA-2 and POL-2 observations planned as part of this survey, and to planned Herschel key programmes.

ACKNOWLEDGMENTS

The JCMT is operated by The Joint Astronomy Centre on behalf of the Science and Technology Facilities Council of the United Kingdom, the Netherlands Organisation for Scientific Research and the National Research Council of Canada. JFR would like to thank E. Rosolowsky for help and advice on analysing the dense cores. JFR acknowledges the support of the MICINN under grant number ESP2007-65812-C02-C01.
