ARTICLE

Prostaglandin E2 mediates sensory nerve regulation of bone homeostasis

Hao Chen, Bo Hu, Xiao Lv, Shouan Zhu, Gehua Zhen, Mei Wan, Amit Jain, Bo Gao, Yu Chai, Mi Yang, Xiao Wang, Ruoxian Deng, Lei Wang, Yong Cao, Shuangfei Ni, Shen Liu, Wen Yuan, Huaijiang Chen, Xinzhong Dong, Yun Guan, Huilin Yang & Xu Cao

Whether sensory nerve can sense bone density or metabolic activity to control bone homeostasis is unknown. Here we found prostaglandin E2 (PGE2) secreted by osteoblastic cells activates PGE2 receptor 4 (EP4) in sensory nerves to regulate bone formation by inhibiting sympathetic activity through the central nervous system. PGE2 secreted by osteoblasts increases when bone density decreases as demonstrated in osteoporotic animal models. Ablation of sensory nerves erodes the skeletal integrity. Specifically, knockout of the EP4 gene in the sensory nerves or cyclooxygenase-2 (COX2) in the osteoblastic cells significantly reduces bone volume in adult mice. Sympathetic tone is increased in sensory denervation models, and propranolol, a β2-adrenergic antagonist, rescues bone loss. Furthermore, injection of SW033291, a small molecule to increase PGE2 level locally, significantly boosts bone formation, whereas the effect is obstructed in EP4 knockout mice. Thus, we show that PGE2 mediates sensory nerve to control bone homeostasis and promote regeneration.
Sensory nerves are innervated in peripheral tissues, including skin, joint, respiratory, and gastrointestinal tissues, to sense stimuli inside or outside the body, such as pain, temperature, odor, and taste. The signals collected from sensory nerve endings are processed in the central nervous system to initiate physiological responses. Bone is the largest organ, accounting for more than 80% of body weight. Bone is also an endocrine organ that regulates calcium and mineral metabolism, glucose, fatty acids, and even cancer metastasis by interacting with other tissues. The skeleton has abundant sensory and sympathetic innervations and interacts with the central nervous system. Sympathetic nerves induce catabolic activity in bone through serotonin and MAPK-response element binding protein (CREB) signaling in the hypothalamus. Specific deletion of sensory nerves in bone impairs bone mass accrual and significantly decreases post-injury bone regeneration. These observations indicate that sensory nerves sense changes in bone density, mechanical stress, and metabolic activity to control bone homeostasis.

Based on the evidence, one or more molecules should transmit signals of changes in bone to sensory nerve fibers. Cyclooxygenase activity and prostaglandins are known to mediate skeletal metabolism and inflammation. Among prostaglandins, prostaglandin E2 (PGE2) is a multifunctional molecule whose production is controlled by the limiting enzyme cyclooxygenase (COX). Evidence shows that PGE2 can elicit primary pain and prolong nociceptor sensitization. Non-steroidal anti-inflammatory drugs and COX2 selective inhibitors are the current major inflammatory drugs to treat musculoskeletal pain. A multicenter study revealed that COX2 selective inhibitor is associated with lower bone mineral density (BMD) in men; whereas, in postmenopausal women it promotes BMD, implicating PGE2 in the regulation of bone.

The 15-hydroxyprostaglandin dehydrogenase gene (HPGD) encodes a NAD+–dependent 15-hydroxyprostaglandin dehydrogenase (15-PGDH), which catalyzes PGE2. Mutation of this gene impairs the degradation of PGE2. HPGD mutant mice showed an increased PGE2 level in vivo, which can effectively promote regeneration in different tissues. Interestingly, patients with HPGD mutation have presented with subperiosteal new bone formation. PGE2 is also potent in stimulating bone formation, and its bone anabolic effect is believed to be through its receptor EP4 in the osteoblasts. However, conditional knockout of the prostaglandin E receptor 4 gene (EP4) in osteoblastic cells did not impair bone density, implying that the bone formation effect of PGE2 does not act through osteoblasts. In pathological conditions of bone loss during aging or after menopause, the impaired function of sensory nerves and elevated PGE2 level appear simultaneously. Thus, PGE2-induced pain may reflect its activation of sensory nerves to transmit a signal of bone density to maintain bone homeostasis.

Here in this study, we report that bone density regulates the level of PGE2 secreted by osteoblasts. Deletion of EP4 in sensory nerves or COX2 in osteoblasts significantly decreases bone mass. Elevation of PGE2 by inhibiting 15-PGDH promotes bone regeneration. PGE2 regulates osteoblast bone formation by activation of sensory nerves in a sympathetic nerve feedback manner.

**Results**

**Sensory denervation reduces osteoblastic bone formation.** To investigate the effect of sensory nerve in bone, we created a sensory denervation mouse model (TrkA+/−) by crossing sensory nerve-specific cre (Advillin-cre) mice with nerve growth factor (NGF) receptor TrkA floxed (TrkAwt) mice. Quantitative polymerase chain reaction (qPCR) and immunofluorescent staining of TrkA in the dorsal root ganglion (DRG) neurons and the other tissues isolated from the TrkA+/− (TrkAwt) mice validated the knockdown efficiency and specificity of the TrkA gene in the TrkA+/− mice (Supplementary Figure 1). Furthermore, immunostaining of femur sections showed that most calcitonin gene-related peptide (CGRP) sensory nerve fibers were eliminated in the TrkA+/− (TrkAwt) mice (Supplementary Figure 1). Significant bone loss was observed in 12-week-old TrkA+/− (TrkAwt) mice relative to their wild-type (WT) littermates in μCT analysis (Fig. 1b), while no significant bone volume decrease was found of 4-week-old age (Supplementary Figure 2), indicating an essential role of sensory nerve for bone homeostasis in adults. The number of osteocalcin+ osteoblasts was significantly lower in TrkA+/− (TrkAwt) mice relative to their WT littermates; whereas, the number of tarsal acidic phosphatase (TRAP)+ osteoclasts was not different (Fig. 1c). Trichrome staining showed decreased osteoid in TrkA+/− (TrkAwt) mice (Fig. 1d). Accordingly, the serum level of osteocalcin, a marker of osteoblastic bone formation, was significantly lower, and the level of osteostat bone resorption marker carboxy-terminal collagen crosslinks (CTX) was not different in TrkA+/− (TrkAwt) mice (Fig. 1e). Calcine double labeling confirmed the reduced bone formation and mineral apposition rate (Fig. 1f).

To examine whether sensory nerves maintain bone homeostasis through bone remodeling in adult mice, we established inducible sensory denervation in iDTR+/− mice by crossing Advillin-cre mice with iDTRwt mice. Sensory denervation was effectively induced in adult iDTR+/− mice by injection of 1 ug per kg diphtheria toxin (DTX) three times a week for four weeks (Fig. 2a). Significant bone loss was observed using μCT analysis (Fig. 2b). Similarly, the number of osteoblasts, amount of osteoid, and serum osteocalcin level were significantly decreased; whereas, the number of osteoclasts and serum CTX level were unchanged relative to the vehicle group (Fig. 2c, e). The calcine double-labeling experiment confirmed that bone formation and mineral apposition rate were reduced (Fig. 2f). Moreover, sensory innervations and bone mass also decreased in the vertebrae of iDTR+/− mice injected with DTX relative to the vehicle-treated mice (Fig. 2g, i and Supplementary Figure 3, D–E). Because neural changes other than those in the sensory nervous system can affect bone metabolism indirectly, we performed pole tests and grip strength tests with TrkA+/− and iDTR+/− mice injected with DTX. No motor neural activity was influenced in these two mouse models (Supplementary Figure 4). Thus, sensory nerve regulates bone homeostasis through osteoblasts during bone remodeling.

**Knockout of EP4 receptor in sensory nerve induces bone loss.** Because PGE2 is known to stimulate osteoblastic bone formation, we measured PGE2 levels in the serum of both global and inducible sensory denervation mice. Interestingly, PGE2 levels increased significantly in all the denervation mouse models (Fig. 3a). The results prompted us to examine whether PGE2 mediates sensory nerve in regulation of osteoblast bone formation. We found that bone density was negatively correlated with PGE2 levels, and that PGE2 levels increased in aged or the other osteoporotic mice (Fig. 3a). Immunohistochemical analysis also showed that expression of COX2 in femur osteoblasts, the PGE2 production-limiting enzyme, increased in the sensory denervation.
O VX and aged mice (Fig. 3b, c). As EP4 is the primary receptor of PGE2 for bone formation, we further co-immunostained of EP4 or CGRP in O VX and aged mice femurs. In O VX mice, we observed a significant reduction of CGRP⁺ sensory fibers two weeks post O VX surgery (Fig. 3d, e). Interestingly, loss of EP4 expression in the sensory fibers of aged mouse bone marrow with no significant decrease of the CGRP⁺ nerve fibers (Fig. 3f, g). We then induced ablation of EP4 in sensory nerves using adult EP4Avil⁻/⁻ mice by crossing Advillin-cre mice with EP4wt mice to validate of EP4 function in sensory nerves. qPCR analysis and immunostaining of EP4 confirmed that EP4 deletion was specifically in nerve (Supplementary Figure 5). Co-immunofluorescent staining of EP4 with CGRP showed that EP4 was expressed in bone sensory nerves, confirming that EP4 was efficiently deleted from sensory nerves in the bone marrow of EP4Avil⁻/⁻ mice (Fig. 4a).

Both trabecular bone and cortical bone decreased significantly in 12-week EP4-ablated mice (Fig. 4b, c, Supplementary Figure 6). Pole tests and grip strength tests showed no changes in motor neural activity (Supplementary Figure 7). PGE2 levels in the serum and COX2 expression in osteoblasts increased (Fig. 4d, e), suggesting a compensatory increase of the ligand PGE2 in response to EP4 knockout in sensory nerves. Similar to the two sensory denervation models, in EP4Avil⁻/⁻ mice, the number of osteoblasts decreased (but the serum osteocalcin level showed no statistical significance), with no changes in osteoclast number or bone degradation marker CTX (Fig. 4f, g). Importantly, PGE2 induced significant bone formation in wild-type mice was abolished in EP4Avil⁻/⁻ mice, as demonstrated in trichrome and double-labeling experiments (Fig. 3h, i). As EP4 expression is also known to express in osteoblasts, osteoblastic cell-specific knockout EP4 mice were generated by crossing EP4wt mice with

osteocalcin-cre (OC-cre) mice (Supplementary Figure 8, A). However, μCT analysis did not reveal significant bone volume change in EP4\textsubscript{OC}\textsuperscript{−/−} mice (Supplementary Figure 8, B). These results show that PGE2-induced osteoblastic bone formation is signaled through EP4 in the sensory nerves.

**PGE2 mediates sensory nerve induced osteogenesis.** To examine whether PGE2 is secreted primarily by osteoblastic cells for sensory nerve regulation of bone, we further generated conditional knockout COX2 mice in the osteoblastic cells (COX2\textsubscript{OC}\textsuperscript{−/−}) by crossing COX2\textsuperscript{wt} mice with OC-cre mice to eliminate PGE2 secretion by osteocytes. Pole tests and grip strength tests showed no effect on motor activity, indicating that knockout of COX2 did not affect global neural activity (Supplementary Figure 9). As in EP4 knockout mice, trabecular and cortical bone decreased while body weight remained unchanged over time in COX2\textsubscript{OC}\textsuperscript{−/−} mice relative to their COX2\textsuperscript{wt} littermates (Fig. 5a, b, Supplementary Figure 10). COX2 staining of the mouse femurs showed no effect on motor activity, indicating that knockout of COX2 does not affect global neural activity (Supplementary Figure 11). This suggests that PGE2 secreted by osteoblastic cells in active bone remodeling sites is essential because the bone marrow PGE2, instead of the serum PGE2, is stimulated in active bone remodeling sites with Ocn\textsuperscript{−/−} mice injected with vehicle or DTX. Scale bar, 100 μm. g Representative images of immunofluorescence staining and quantitative analysis of the CGRP\textsuperscript{+} sensory nerves (green) in the vertebra of DTR\textsubscript{Avl}\textsuperscript{−/−} mice injected with vehicle or DTX. largely secreted by osteoblasts, mediates sensory nerve-regulated osteoblastic bone formation.

PGE2 induces hypothalamic CREB signaling for osteogenesis. CREB signaling in the hypothalamus is crucial for the regulation of skeletal homeostasis\(^\text{10}\). To examine whether PGE2 could activate EP4 in sensory nerves through the ventromedial nucleus of the hypothalamus (VMH), we examined the effect of PGE2 on DRG neurons and the phosphorylation of CREB in the VMH of EP4Avil\(^{-/-}\) mice. Calcium imaging showed more illuminated DRG neurons in those pre-treated with PGE2 relative to vehicle-treated neurons, whereas DRG neuron activation was reduced significantly in EP4Avil\(^{-/-}\) mice with or without PGE2 pre-treatment (Fig. 6a). Western blot analysis of the hypothalamus showed that phosphorylation of CREB increased gradually and peaked at 6 h after injection (Supplementary Figure 12, A). Immunostaining of VMH sections showed that phosphorylation of CREB decreased significantly in EP4Avil\(^{-/-}\) mice relative to their WT littermates (Fig. 6b). PGE2 was then injected into EP4Avil\(^{-/-}\) mice and their WT littermates to further test whether the central regulation is sensory nerve-dependent. Immunostaining of hypothalamus sections showed CREB phosphorylation increased significantly in mouse VMH 6 h after injection,
whereas, PGE2-induced CREB phosphorylation in VMH was abolished in EP4Avil−/− mice (Fig. 6b). Then, EP1/3 and EP4 agonists were injected to examine whether EP4 receptor is responsible for PGE2-induced CREB signaling in VMH. EP1/3 agonist did not increase phosphorylation of CREB in VMH, whereas EP4 agonist significantly increased pCREB level relative to vehicle-treated mice (Supplementary Figure 12, B), indicating that EP4 in sensory nerves is specific for PGE2-induced CREB phosphorylation in VMH.

The activation of CREB signaling in the hypothalamus has been shown to suppress sympathetic tone10,13. Indeed, uncoupling protein 1 gene (UCP1) expression in adipose tissue and epinephrine concentrations in urine increased significantly in the EP4Avil−/− mice and COX2OC−/− mice relative to their WT littermates, indicating higher sympathetic tone in these two mouse models (Fig. 6c, d). Immunostaining of the femur sections showed small, flattened osteoblasts on the bone surface (Fig. 6e, f) and reduced Ki67 expression in osterix+ cells in both

**COX2OC−/− and EP4Avil−/− mice**, indicating that increased sympathetic tone suppress osteoblastic activity (Fig. 6g, h). To confirm that the increased sympathetic activity leads to bone loss, we injected propranolol, a β2-adrenergic antagonist, into EP4Avil−/− and COX2OC−/− mice. Propranolol partially rescued bone phenotype of these two knockout mice (Fig. 6i and Supplementary Figure 13). These results indicate that sympathetic tone regulates osteoblast differentiation through EP4 activation of sensory nerve.

We also tested if PGE2 secretion is regulated by mechanical loading as mechanical loading has been shown to regulate bone homeostasis through central regulation of sympathetic tone.35,36 Mechanical loading was applied to C57B/L6 mice and bone marrow PGE2 levels were measured. The result showed that PGE2 levels significantly increased in the loading group compared with the control group (Supplementary Figure 14A). COX2 expression in osteoblasts was examined in osteoblastic MC3T3-E1 cells cultured on high-extension silicon rubber dishes with applied compression force to mimic mechanical loads on bone. Western blot analysis showed that COX2 expression increased when the compression force applied (Supplementary Figure 14B). In addition, bone marrow PGE2 levels in COX2OC−/− mice and their littermates with unloading by tail suspension were measured. The results showed that bone marrow PGE2 significantly decreased in wild-type mice in tail suspension conditions while no change was observed in COX2OC−/− mice with (Supplementary Figure 14C). These results suggest that osteoblasts secrete PGE2 secretion in responsible to mechanical loading.

**PGE2 promotes skeletal regeneration through sensory nerves.** PGE2 has been reported recently to potentiate regeneration of multiple tissues.25 To investigate whether PGE2 induces tissue regeneration through sensory nerves, we assessed whether PGE2 induces bone regeneration. 15-PGDH inhibitor SW033291 was injected into EP4Avil−/− and EPwt mice that had undergone surgical ablation of trabecular bone to examine the effects of an increase in local PGE2 on bone regeneration. Elevation of local PGE2 boosted trabecular bone regeneration significantly in EP4wt mice, indicating that increased sympathetic activity leads to bone loss, we injected propranolol, a β2-adrenergic antagonist, into EP4Avil−/− and COX2OC−/− mice. Propranolol partially rescued bone phenotype of these two knockout mice (Fig. 6i and Supplementary Figure 13). These results indicate that sympathetic tone regulates osteoblast differentiation through EP4 activation of sensory nerve.

We also tested if PGE2 secretion is regulated by mechanical loading as mechanical loading has been shown to regulate bone homeostasis through central regulation of sympathetic tone.35,36 Mechanical loading was applied to C57B/L6 mice and bone marrow PGE2 levels were measured. The result showed that PGE2 levels significantly increased in the loading group compared with the control group (Supplementary Figure 14A). COX2 expression in osteoblasts was examined in osteoblastic MC3T3-E1 cells cultured on high-extension silicon rubber dishes with applied compression force to mimic mechanical loads on bone. Western blot analysis showed that COX2 expression increased when the compression force applied (Supplementary Figure 14B). In addition, bone marrow PGE2 levels in COX2OC−/− mice and their littermates with unloading by tail suspension were measured. The results showed that bone marrow PGE2 significantly decreased in wild-type mice in tail suspension conditions while no change was observed in COX2OC−/− mice with (Supplementary Figure 14C). These results suggest that osteoblasts secrete PGE2 secretion in responsible to mechanical loading.

**PGE2 promotes skeletal regeneration through sensory nerves.** PGE2 has been reported recently to potentiate regeneration of multiple tissues.25 To investigate whether PGE2 induces tissue regeneration through sensory nerves, we assessed whether PGE2 induces bone regeneration. 15-PGDH inhibitor SW033291 was injected into EP4Avil−/− and EPwt mice that had undergone surgical ablation of trabecular bone to examine the effects of an increase in local PGE2 on bone regeneration. Elevation of local PGE2 boosted trabecular bone regeneration significantly in EP4wt mice.
mice injected with SW033291 relative to vehicle-treated controls, as shown by μCT (Fig. 7a) and hematoxylin-eosin (HE) staining (Fig. 7b). However, the regeneration of trabecular bone by SW033291 was obstructed in EP4Avil−/− mice (Fig. 7a, b). As known that CD31hi Endomucinhhi type H vessel couples with active new bone formation37,38, we further evaluated its expression and found that the type H vessel growth was significantly increased in the regeneration area of EP4wt mice treated with SW033291. However, type H vessels were almost undetectable in EP4Avil−/− mice with or without injection of SW033291 (Fig. 7b). Thus, PGE2 stimulates bone regeneration through sensory nerves.

To further investigate whether PGE2 induces regeneration by sensory nerves of tissues other than bone, we performed partial hepatectomy in TrkAAvil−/− mice and their WT littermates treated with SW033291 or vehicle. BrdU and Ki67 staining of liver sections with partial hepatectomy showed that the regeneration rate decreased significantly in TrkAAgil−/− mice treated with SW033291 relative to their WT littermates (Supplementary Figure 15). Staining of CGRP in the regeneration areas confirmed that sensory innervation in the liver was significantly reduced in TrkAAvil−/− mice. These results show that PGE2 induces bone regeneration dependent on sensory nerves, and that sensory nerves are likely involved in regeneration of various tissues.

Discussion
As the largest organ, bone mechanically supports the body. Changes in bone can increase the risk of bone fracture. It is imperative to monitor changes in bone density to maintain bone homeostasis. We have found that PGE2 levels are elevated during decline in bone density in various animal models, including osteoporotic mice. The current study shows that sensory nerves sense bone density through the concentration of PGE2. The signals from PGE2, by bonding with EP4 in the sensory nerves, regulate sympathetic nerve activity for osteoblastic bone formation through the central nervous system. High sympathetic tone is
known to stimulate osteoclastic bone resorption by increasing osteoclast activation of Rankl (receptor activator of nuclear factor kappa-B ligand). Sensory nerve activated by PGE2 promotes osteoclast proliferation and differentiation by tuning down sympathetic nerve activity. Therefore, the sympathetic nerve can regulate both osteoclastogenesis for bone resorption and osteoblast differentiation for bone formation, depending on the levels of its tone. Interestingly, deletion of sensory nerves did not affect bone development but did reduce bone volume in adult mice. Importantly, sensory nerves regulate bone formation by osteoblast secretion of PGE2 in the bone remodeling microenvironment. Thus, the primary function of sensory nerves in bone is to maintain and protect bone homeostasis by sensing PGE2 in bone.

PTH and mechanical loading are known to stimulate the bone remodeling and TGFβ couples the process. These factors of bone remodeling have been reported to increase PGE2 levels in the bone marrow or cultured osteoblasts49-52, indicating that factors in regulation of bone remodeling also promotes osteoblast secretion of PGE2. Moreover, our data and previous report demonstrate that mechanical loading stimulates PGE2 levels in the skeletal system53,36,42. In osteoporotic conditions, the relative mechanical load per bone remodeling unit area increases, which promotes osteoblasts on the bone surface to secrete more PGE2 to stimulate sensory nerves. A recent study showed that an increase in PGE2 through inhibition of its degradation enzyme activity with a small molecule (SW033291) promotes tissue regeneration in various tissues, including liver, intestine, and hematopoietic cells in the bone marrow25. We too found that the increase in PGE2 caused by SW033291 promotes bone regeneration.

Importantly, the effect on bone regeneration was eliminated when EP4 in the sensory nerves was knocked out in EP4Avil−/− mice. Similarly, liver regeneration was also diminished in TrkA−/- mice with or without injection of SW033291. It is documented that sensory and sympathetic nerves are both innervated in the liver44, and active neural sprouting was observed after partial heptectomy, suggesting an essential role of sensory nerves in liver regeneration45. However, we observed liver regeneration rate was not altered in the EP4Avil−/− mice in compare with their wild type littermates, neither does SW033291 treatment show any difference between these two groups, indicating that sensory nerve is indispensable in liver regeneration, but the mechanism is not through PGE2-EP4 signaling on sensory nerves. These results suggest that PGE2-EP4 signaling on sensory nerve seems to maintain the integrity of skeletal system specifically.

Clinical studies have reported decreased BMD in patients with long-term use of non-steroidal anti-inflammatory drugs, which inhibit COX2 activity to reduce the production of PGE223. Evidence shows that PGE2 stimulates osteoblast differentiation by activating cAMP signaling through G protein-coupled EP4 receptor18. However, knockout of EP4 receptor in osteoblasts with no skeletal phenotype indicates that PGE2-induced bone formation is not caused by direct signaling through osteoblasts. Our data show that deletion of EP4 receptor in peripheral sensory nerves leads to decreased bone density, and that injection of PGE2 is no longer able to stimulate bone formation. It has been well documented that sympathetic tone was tuned down with PGE2 injection peripherally, and sympathetic nerve action on bone metabolism has been shown through hypothalamic regulation12,13,46,47. Indeed, we show that injection of PGE2 stimulated phosphorylation of CREB in the hypothalamus, which was inhibited by knockout of EP4 in the peripheral sensory nerves (EP4Avil−/−), which is the evidence of CNS involvement. More than 10% of clinical patients with central nervous system injury were observed to have heterotopic ossification48. These findings show that sensory nerve signals from PGE2 in bone remodeling sites are circled back through regulation by sympathetic nerves. However, it is still unclear whether PGE2 signaling from the bone remodeling sites regulate sympathetic tone through DRG, hypothalamus and both feedback regulation of sympathetic activity is spatially specific. Our data suggest that the feedback is likely involved both DRG and hypothalamus. It is documented that sensory signals from the viscera are carried to the central nervous system by spinal and cranial afferents49. Sensory afferents from visceral and somatic sensory nerves converge onto common second-order neurons within the spinal dorsal horn, and a subset of these neurons convey the convergent signals to the diencephalon via the anterolateral spinothalamic tract50,51. This viscerotopically organized pathway provides direct and relayed inputs to the hypothalamus and other central nervous locations52,53. Therefore, the similar pathway is possibly employed in the PGE2-induced CREB phosphorylation in the hypothalamus. Herein, sensory nerve regulation appears to involve precise temporal-spatial action controlled by sympathetic nerves in the bone remodeling microenvironment, and the central nervous system likely coordinates the activities of different tissues for energy and calcium metabolism of bone formation.

Methods

Mice and in vivo treatment. The iDTβi[fl] and Dentin matrix acidic phosphoprotein 1-Cre (DMP1-Cre) mice were purchased from the Jackson Laboratory. The Advl-rCre (Avil-Cre) mouse strain was kindly provided by Xingzhong Dong (The Johns Hopkins University, The osteocalcin-Cre (OC-Cre) mice were obtained from Thomas J. Clemens (The Johns Hopkins University). The TrkAfl mice were obtained from David D. Ginty (Harvard Medical School). The COX2fl mice were provided by Harvey Hershman (University of California, Los Angeles). The EP4fl mice were obtained from Brian L. Kelsall (National Institutes of Health). Heterozygous Avil-Cre male mice (female Avil-Cre mice were not used to breed in case for the leakage of TrkA protein into the eggs) were crossed with a TrkAfl, EP4fl, or iDTβifl mouse. The offspring were intercrossed to generate the following genotypes: wild type (referred as WT in the text), Avil-Cre (Cre recombinase expressed driven by Advlin promoter), TrkAfl (mice homogzyous for TrkA floxed allele are referred to as TrkAfl+ in the text), EP4fl (referred to as EP4fl+ in the text), iDTβifl (conditional deletion of EP4 receptor in Advlin lineage or referred to as EP4Avil−/− in the text), Avil-Cre::EP4fl (referred to as TrkAflAvil−/− in the text), and Avil-Cre::iDTβi (referred to as iDTβiAvil−/− in the text). Heterozygous Oc-Cre or DMP1-Cre mice were crossed with a COX2fl mouse; the offspring were intercrossed to generate the following genotypes: WT, Oc-Cre, DMP1-Cre, COX2fl (referred to as COX2fl+ in the text), Oc-Cre:EP4fl (referred to as COX2flEP4fl+ in the text), and DMP1-Cre::COX2fl (referred to as COX2flDMP1fl in the text) mice. Heterozygous Oc-Cre or Avil-Cre mice were crossed with a EP4fl mouse, the offspring were intercrossed to generate the following genotypes: WT, Oc-Cre, DMP1-Cre, COX2fl (referred to as COX2fl+ in the text), Oc-Cre:EP4fl (referred to as COX2flEP4fl+ in the text), and DMP1-Cre::COX2fl (referred to as COX2flDMP1fl in the text) mice. The drugs and compounds used in this study are as follows: diphtheria toxin (DTX, Sigma-Aldrich, D0564); PGE2 (Cayman Chemical, 14010); EP1/3 agonist (Cayman Chemical, 14810); EP4 agonist (Cayman Chemical, 15080); propranolol hydrochloride (Sigma-Aldrich, 157605); norpheniramine (Sigma-Aldrich, A7725); and SW033291 (Selleck, S7900). Dosages and time courses are noted in the corresponding text and figure legends.
Behavioral analysis. Pole tests and grip strength tests were performed to evaluate motor neural activity changes in TrkAAavil and COX2OC−/− mice. Four animals were tested between 15:00 and 16:00, ensuring the lighting conditions were similar. For the pole test, a 9-mm-diameter metal rod with bandage gauze was used as the pole. The time for a mouse to turn and the total time for it to reach the base of the pole was recorded. Before the test, the mice were trained for three consecutive days, and each training session consisted of three test trials. For grip strength, mouse grip strength was measured as maximum holding force generated by the mice (Biosed, USA). Mice were placed to grasp a metal grid with their forelimbs or hindlimbs. The tail was pulled gently, and the maximum holding force was recorded by the force transducer when the mice released their grasp on the grid. The peak holding strength was recorded digitally and displayed in grams.

μCT analyses. The femurs were harvested from mice, and the soft tissue around the bone was removed, followed by fixation overnight using 4% paraformaldehyde. μCT analyses were performed by using a high-resolution μCT scanner (SkyScan, 1174). The voltage of the scanning procedure was 65 kV with a 153-μm current. The resolution was set to 8.7 μm per pixel. Reconstruction software (NRecon, v1.6, SkyScan), data analysis software (CTan, v1.9, SkyScan), and 3D modeling visualization software (CTVld, v2.0, SkyScan) were used to analyze the diaphyseal cortical bone and the metaphyseal trabecular bone parameters of the femurs. We created cross-sectional images of the femur to perform 2D analyses of the cortical bone and 3D analyses of the trabecular bone. The region of interest (ROI) of the trabecular bone was drawn beginning from 5% of the femur length proximal to the distal metaphyseal growth plate and extending proximally for another 5% of the total femur length. The trabecular bone volume fraction (BV/TV), trabecular thickness (Tb. Th), trabecular number (Tb. N), and trabecular separation (Tb. Sp) were collected from the μCT images data and used to represent the trabecular bone parameters. The cortical bone ROI was drawn beginning from 20% of femur length proximal to distal metaphyseal growth plate and extending proximally to another 10% of the total femur length. The cortical thickness (Ct. Th), periosteal perimeter (Ps. Pm), and endosteal perimeter (Es. Pm) were collected from the 2D analyses data and used to represent the cortical bone parameters.

Immunohistochemistry, immunofluorescence and histomorphometry. The femurs were collected and fixed in 4% paraformaldehyde overnight and decalcified by using 10% EDTA (pH 7.4) (Amresco, 1015) for 21 days. The samples were then dehydrated with 30%, 50%, 70%, 80%, 90%, 96%, and 100% ethanol for 4 h and embedded in paraffin or optimal cutting temperature compound (Sakura Finetek). We prepared 4-μm-thick sections of the femurs for hematoxylin and eosin staining. The femurs were fixed for 4 h with 4% paraformaldehyde at 4°C and then decalciﬁed with 10 mM EDTA at pH 7.4 for 24 h with constant shaking. The samples were dehydrated in 20% sucrose and 2% polyvinylpyrrolidone (PVP) solution for 24 h and embedded in 8% gelatin (Sigma-Aldrich, G1890) in the presence of 20% sucrose and 2% PVP. Forty-μm-thick coronal-oriented sections of the femurs were obtained. For brain section preparation, the whole brain was harvested from euthanized mice and fixed with 4% paraformaldehyde for 30 min. Then, the tissue was dehydrated with 20% sucrose for 24 h and stained.

Immunostaining was performed using standard protocol. Briefly, the sections were incubated with primary antibodies to mouse osteoblast (Abcam, ab25522, 1:600), osteocalcin (Takara Bio, M173, 1:200), CD31 (Abcam, ab28326, 1:50), endomucin (Santa Cruz, V7C7, 1:50), K87 (Abcam, ab16867, 1:100), CGRP (Abcam, ab18877, 1:100), COX2 (Abcam, ab92763, 1:100), CREB (Cell Signaling Technology, 9197, 1:100), p-CREB (Abcam, ab32096, 1:100), NF-κB (Millipore, AB5359, 1:500), TrkA (R&D systems, AF1056, 1:1000) and IB4 (Thermo Fisher Scientific, 121411) overnight at 4°C. A horseradish peroxidase–streptavidin detection kit (Dako) was used to detect in immunohistochemical procedures to detect immune–activity, followed by counterstaining with hematoxylin (Dako, S3309). Fluorescence-conjugated secondary antibodies were used in immunofluorescent procedures to detect fluorescent signals after counterstaining with DAPI (Vector, H-1200). We used a Zeiss LSM 780 confocal microscope or an Olympus BX51 microscope for sample image capturing. A BrdU fluorescent procedure was done on all samples to detect cell proliferation. The double-labeling images of undecalciﬁed bone were imaged at 340 and 380 nm after immersion in calcium-free buffer for 1 min.

In vitro and in vivo mechanical loading assays. In vitro-mechanical stretching assay: Osteoblastic MC3T3 cells (stored in our lab) were plated on the home-made high-extension silicon rubber dishes with 4% and 12% morphological change of the dishes. After 24 h, and starved for 4 h. The high-extension silicon rubber dishes were fixed on the home-made mechanical stretching machine and compress the cells with different force levels as controlled by 4% and 12% morphology change of the dishes. After 24 h, the cells lysate was harvested for western blot assay.

In vivo-treadmill assay: C57BL/6 mice were trained for 5 days on treadmill with the protocol of 8m/min, 5° uphill for 10 min per day. Then, we followed the protocol for 14m/min, 14° uphill for 20min per day for formal tests. After 2 weeks, serum and bone marrow were harvested for ELISA assays.

Bone and liver regeneration models. Mice underwent general anesthesia. The bone regeneration model was established as described below. A longitudinal incision was made on the back of mice between the scapulae. The mouse was placed on a home-made mechanical stretching apparatus. The distance between the fulcrum and the distal end of the femur was measured using a dental drill. A 0.6-mm-diameter Kirschner wire was placed to the proximal end of the femur to confirm marrow ablation by radiography. The dislocated patella was reposed, and the skin was sutured after removal of the Kirschner wire. Bone samples were harvested 7 days after bone marrow ablation, as described above.

Partial hepatectomy was used for the liver regeneration model. 10- to 12-week-old male mice were anesthetized, as described above. A partial (two-thirds) hepatectomy was performed by resecting the median and left lateral hepatic lobes. The remnant livers were harvested after mice sacrifice. SW133291 was dissolved in a vehicle of 10% ethanol, 5% Cremophor EL, and 85% dextrose 5% in water.

Statistics. All data analyses were performed using SPSS, version 15.0, software (IBM Corp.). Data are presented as means ± standard error of mean (SEM). For comparisons between two groups, we used two-tailed Student t-tests. For comparisons among multiple groups, we used one-way ANOVA. All inclusion/exclusion criteria were pre-established, and no samples or animals were excluded from the analysis. No statistical method was used to predetermine the sample size. The experiments were randomized. The investigators were not blinded to allocation during experiments and outcome assessment. All relevant data are available from the authors.

Reporting summary. Further information on experimental design is available in the Nature Research Reporting Summary linked to this article.

Data availability
We confirm that all relevant data are available from the authors.
