**ARTICLE INFO**

**Abstract**

The use of ultrasound to intensify the germination process of *Triticum aestivum* L. wheat was studied. This method of controlled germination can be used in several sectors of food industry, in particular in bakery. The effect of low-frequency ultrasound (20 kHz) at different intensities and duration on the germination process of *Triticum aestivum* L. wheat was systematically studied. We have found that 3-minute processing at 227 W/l output reduces the duration of wheat grain germination by 25% (12 ± 2 h) compared to the control samples. The use of ultrasound stimulated γ-aminobutyric acid (GABA) synthesis (18.9 ± 0.5 mg/100 g), increased the antioxidant activity (AOA) (2.86 ± 0.2 mg/g Trolox equivalents) and the amount of flavonoids (0.19 ± 0.03 mg QE/g). The SEM analysis of powder particles of whole-wheat flour made from wheat germinated with ultrasound exposure showed densely packed aggregates of protein matrix. To sum up, controlled ultrasound during wheat grain germination increases the amount of GABA and AOA. The whole-wheat flour is useful for food enrichment.

**Keywords:** Ultrasound, Wheat grain, Germination, γ-Aminobutyric acid, Antioxidant activity, Grain products

1. Introduction

Grain crops germination is actively used in food technology as an effective way to increase their nutritional value. The process of grain germination is known to activate enzymatic systems [1], increase the availability of reducing sugars, free amino acids, including lysine [2], and stimulate the accumulation of γ-aminobutyric acid (GABA) [3] and increase antioxidant activity (AOA) [4].

AOA of germinated grain is closely related to the complex of mitochondrial redox reactions [5]. Release of reactive oxygen species is observed in grain cells at germination, with protection provided by the use of a highly active antioxidant system in the composition of low and high-molecular weight compounds [6].

Among the chemical components synthesized during grain germination, GABA occupies a special place as a substance recommended for the prevention of neurological disorders [7]. GABA attracted more attention due to its biological activities such as lowering blood pressure [8], stimulating immunity enhancement [9], improving brain function and enhancing intelligence [10]. Consumption of food enriched with GABA helps to reduce anxiety [11,12].

In this regard, the search for ways to enhance the amount of substances possessing antioxidant activity and GABA synthesis in plant materials is getting more attention.

The use of ultrasonic processing in food industry is growing [13,14]. Chemat showed the beneficial effects of ultrasound in combination with mechanical kneading on the extraction of flavonoids from plant raw materials [15]. Yang et al. showed that the amount of GABA increased by 43.4% due to ultrasonic treatment (40 kHz, 300 W) during the process of soybean seeds steeping for 30 min [16]. Some studies have shown the possibility of obtaining GABA from germinated grain [7]. Other studies have considered the use of germinated wheat in bakery products as a source of GABA [12]. It is reported that grain products obtained using germinated raw materials are of a softer consistency and sweeter [17].

At the same time, when obtaining food products based on whole-wheat flour from germinated grain, there is a high probability of changing the technological application of the obtained raw materials. The article shows that the increase in enzymatic activity caused by germination has a negative effect on the quality of wheat processing for grinding and baking [18]. However, controlled grain germination yields flour with improved functional properties, including greater bread volume, better texture and other improved sensory bread characteristics and higher pasta elasticity and plasticity [19].

This study reports on the enhancement of bioactive substances,

including GABA during *Triticum aestivum* L. germination by low-frequency ultrasound stimulation. The properties of products derived from germinated grains were also studied.

2. Materials and methods

2.1. Materials

The experimental procedure is presented in Fig. 1. In this study, we used grain of soft spring white wheat (*Triticum aestivum* L.), “Lubava” variety. The grain was grown and harvested (2018) at the experimental farm of Bredinsky district, Chelyabinsk region, Russia (grains non-germinated (GNG)). The protein content was 12.5 ± 0.03 g/100 g in terms of humidity. All grains used in the studies were pre-selected and sorted by length (8.6 ± 0.6 mm) and width (4.8 ± 0.4 mm) using the program for grain phenotyping SeedCounter v. 1.9.5, developed by Novosibirsk State University [20].

All other chemicals used were of analytical grade.

2.2. Obtaining of whole-wheat flour from germinated wheat grain (whole-wheat flour (WWF))

2.2.1. Wheat grain germination

At the preparatory stage the wheat grain was washed five times in running water at a temperature of 20 ± 2 °C to remove contamination products and foreign substances.

The washed grain (500 g) was soaked in water (water to grain ratio of 1:1):

- Control – the wheat grain was kept in water at a temperature of 22 ± 2 °C for 6 h;
- Test – the wheat grain before the soaking stage was exposed to ultrasound (see 2.2.3) and constant kneading (Fig. 2). Ultrasonic treatment (22 ± 1.25 kHz) was performed by means of changing power and duration (75, 113, 151, 189, 265, 303, 341, 379 W/L, intensity for 3, 5, 7 min). After ultrasonic exposure the soaking process was carried out according to the above method.

The samples prepared for germination were placed in chambers (germination box SHPZ, Russia). Germination was carried out at a temperature of 22 ± 2 °C and relative humidity of 95 ± 3%, the germination period was from 16 to 24 h. When the sprout reached the size of 1.5–2 mm in more than 90% of grains, the grain was removed from the chamber and dried (drying box M 720, Russia) at a temperature of 35–40 °C for 10 h until a final moisture content of 8–14% was reached.

2.2.2. Production of whole wheat flour from germinated wheat grain

Whole-wheat flour was made by grinding germinated grain in the laboratory mill Perten 3100, at a fixed rate of 20,000 vol./min. Perten Instruments, Sweden, equipped with a metal mesh of 0.8 mm. The grain was exposed to grinding for 180 sec until the flour particles were stable in size. To equalize the particle size distribution, according to the proposed by Wang et al method, the whole-wheat flour was additionally sifted through a sieve with a cell size of 0.6 mm [21].

2.2.3. Ultrasonic treatment

Volna-M UZTA-0.63/22-OM as ultrasound generator was used for ultrasonic treatment.

Technical specifications of Volna-M UZTA-0.63/22-OM device are the following: ultrasound oscillation frequency is (22 ± 1.65 kHz); power is 630 W; intercity of ultrasound, not less than 10 W/cm²; power supply voltage is (220 ± 22 V AC); maximum continuous operation time is 8 h; diameter of emitting surface is 30 mm; overall dimensions: electronic generator is (300 × 280 × 120 mm), oscillating system is ∅ (80 × 150 mm).

The ultrasonic vibrating system uses annular piezoelectric elements and is made of BTS titanium alloy. Its operating principle is based on high-intensity ultrasonic waves propagating in fluid and in fluid-dispersed substances. The engineering solutions used are protected by Russian Federation patent № 2141386 [22].
2.3. Selection of optimal conditions for grain exposed to US during germination

To establish the optimal modes of ultrasonic effect on the rate of wheat germination the following controlled parameters were determined: germination energy (E) and germination capacity (N). Mathematical planning was carried out using the Statistica 13 program.

2.3.1. Calculation of germination energy and capacity of grain

The germination energy and germination capacity of grains were calculated according to the methodology described in GOST 10968-88. To measure these parameters, 500 grains were taken from the average calculated according to the methodology described in GOST 10968-88. Mathe

matics planning was carried out using the Statistica 13 program.

2.3. Selection of optimal conditions for grain exposed to US during germination

gluten content – AACC 38-12.02 (AACCi, 2010), the dough was kneaded in accordance with the method AACC 54-21.02 (2010) by the Farinograph-AT (Brabender, Germany) [1].

3.2. Measuring the content of γ-aminobutyric acid (GABA)

Germinated wheat grain (1.00 g) was ground with 6 ml of 4% acetic acid. The homogenate was left on the shaker for 1 h and centrifuged at 6000g for 15 min. The supernatant was collected and treated with 4 ml of ethanol, then centrifuged at 17,000g for 20 min. Purified supernatant was boiled out (0.1 MPa, 45 °C). The residues were dissolved in 0.5 ml of distilled water and centrifuged at 3000g for 10 min.

The resulting suspension was filtered through a 0.45 μm membrane filter. 100 μl of filtered supernatant was analyzed using HPLC (Shimadzu Prominance LC-20 Automated liquid chromatography system, Japan) with a reversed phase column Prodigy C 18 (5 μm), an internal diameter of 4.6 × 250 mm, as described by Rossetti and Lombard [24] and Bai et al. [25].

3.3. Total flavonoid content

The total flavonoid content was measured using the procedure described by Shafii et al. [26]: 0.5 ml of sample extract was mixed with 0.1 ml of 10% (w/v) ethanol solution of aluminum chloride, 0.1 ml of 1 M sodium acetate and 4.3 ml of distilled water. After 30 min in the dark, absorption at 415 nm was measured using a Jenway spectrophotometer (6405 UV/Vis, England). Quercetin (0.01–0.5 mg L⁻¹; R₂ = 0.997) was used as the standard, and the results were expressed in mcg-1-quercetin equivalents.

3.4. Antioxidant activity measuring

Radical analysis (DPPH). Activity of radical absorption in the samples was measured using 2,2-diphenyl-1-picrylhydrazyl (DPPH) [27]. The extracts (0.5 ml) were mixed with 3.6 ml of radical solution (0.025 g DPPH in 100 ml ethanol). The absorbance of the extract sample was measured using a Jenway spectrophotometer (6405 UV/Vis, England) at 515 nm. Trolox (6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid) (10–100 mg/l; R₂ = 0.988) was used as standard, and the results were expressed in mcg-1 Trolox equivalents.

3.5. Evaluation of antioxidant activity by the intensity of AOF generation

A cell model of induced generation of active oxygen forms (AOF) in human undifferentiated neuroblastoma SH-SYSY cell culture was used to evaluate the antioxidant activity of the studied samples.

DMEM (Gibco, UK) medium with addition of 10% embryonic bovine serum (Gibco, New Zealand) was used for cell cultivation. A fluorescent dye 2,7-dichlorodihydrofluorescein-diacetate (DCFH2-DA) was used to evaluate the intensity of the AOF generation in neuroblastoma cells.
(bovine embryonic serum Gibco, New Zealand). The dye was loaded into
the cells for 30 min at a temperature of 37 °C. The dye concentration was
10 μm. Incubation period with samples was 2 h, after that the cells were
washed. Then a phorbol ester (PMA, phorbol-12-myristate-13-acetate)
was added to the cell culture to induce the active oxygen forms gener-
ation. All experiments were performed in HBSS (Hank’s balanced salt
solution) with the addition of HEPES to maintain buffer capacity.

Fluorescence was recorded using a fluorescent tablet reader Tecan
Spark 10 M with a thermostatic camera. To visualize cell cultures with
fluorescence microscopy, we used a system based on an inverted
motorized fluorescent microscope Leica DMI6000B, with a monochrome
CCD camera HAMAMATSU C9100, a light source Leica EL6000 with a
high-pressure mercury lamp HBO 103 W/2 with a lens Leica HCX PL
APO lambda blue 63.0 × 1.40 Oil.

3.6. Statistical processing of results

The studies were carried out in threefold repetition. Grain ger-
mation, whole-wheat flour and bread samples production were carried
out under the same conditions to ensure the accuracy of the results.
Experimental data were processed by methods of mathematical statistics
using Microsoft Excel, MathCad and Statistica 13. The obtained data are
presented with a confidence factor of 0.95.

4. Results

4.1. Analysis of ultrasonic effect on the germination rate

The germination rate of grain is important for the technological
process of production as an economic factor. Since it is important to get a
product of high quality, the process of grain germination should be
under control. The use of ultrasound for grain processing requires a clear
dosage to minimize the risks of negative changes. The power (P) and
duration (t) of ultrasonic exposure (USE) are determining factors that
can stimulate the vitality inherited by nature in every cultivated crop.

As part of the research, we compiled a large amount of data with
successive variations in power (P = 76, 113, 151, 189, 227, 265, 302,
340, 378 W/L) and duration of ultrasonic exposure (t = 3, 5 and 7 min).
We used germination energy (E) and germination capacity (N) as eval-
uation criteria to establish applicable ultrasound modes. The graphs of
the obtained dependences (Fig. 3) showed that the dependence curve is
divided into 2 sections. E and N increase in the first section and decrease
in the second. The dependences pass through the maximum at ultrasonic
power of ~227 W/l. It should be noted that the responses of E and N
correlate well with each other (R = 0.994).

Processing with two piecewise continuous functions gives Eq. (1) for
the first section:

\[ E = 80.9 + 0.0417 \cdot P \]  

Eq. (2) for the second section:

\[ E = 9.9 - 879.2 \cdot \exp(-0.006981 \cdot P) \]

The intersection point corresponds to P = 202 ± 15 W/l and E = 94.5
± 6.9%. The correlation coefficient of the calculated and experimental
values is 0.975. The standard deviation is 6.9%.

For value N, Eq. (3) of the first section has the form:

\[ N = 82.6 + 0.0425 \cdot P \]

Eq. (4) for the second section:

\[ N = 18.9 - 303.9 \cdot \exp(-0.004245 \cdot P) \]

The intersection point is P = 194 ± 10 W/l and E = 96.4 ± 5.2%.
The correlation coefficient of the calculated and experimental values
is 0.973. The standard deviation is 5.2%.

We have not found a statistically significant dependence of germi-
nation energy and germination capacity on the time of ultrasonic
exposure (Fig. 3c and d). Taking into account the technological capa-
Bilities of the device, in further experiments we used the mode 227 W/l
with 3 min of exposure.

This mode was used to study the effect of ultrasound on the activity
of the enzyme α-amylase (the Hagberg falling number) in order to
determine the preferable duration of Triticum aestivum L. germina-
tion. As the objects of the study, we chose:

WWF\text{contr} – whole-wheat flour from germinated wheat grains ob-
tained by soaking for 6 h at a water temperature of 22 ± 2 °C and
germinating for 16 h at a relative humidity of 95 ± 3%, followed by
drying to a moisture content of not more than 14%.

WWF\text{us} – whole-wheat flour from germinated wheat grain after
preliminary US exposure, followed by soaking for 6 h at a water
temperature of $22 \pm 2^\circ$C, germinating for 16 h at a relative humidity of $95 \pm 3\%$ and drying to a moisture content of not more than 14%.

4.2. Change in the falling number (FN)

The dough should contain a certain amount of $\alpha$-amylase to break down starch into amylopectin, but in a case of an excessive amount of this enzyme, starch can completely dissolve, which causes defects in the final product. $\alpha$-amylase can react with starch throughout the entire chain of molecules and create smaller chains of various lengths, which leads to a sharp decrease in viscosity and inverse curvilinear relationship between its enzymatic activity and the FN value [28]. According to the scientific data, the FN value $\sim 60$ is characteristic of the $\alpha$-amylase high activity (bread with sticky crumb, of smaller size, dark in color, contains large cavities); FN $\sim 250$ – normal activity (bread of good quality); FN $\sim 400$ – low activity (dry bread, of smaller size, perishable). Therefore, the determination of the FN grinding of grain batches will help to improve their technological properties.

In this research, the FN value change was determined during the wheat grain germination in order to control the rate of this process. The results obtained (Fig. 4) describe a decrease in the FN value during germinating. The initial FN values of wheat samples were $312 \pm 4$ s; during germination these values decreased multiple times. The ultrasonic exposure provides a high germination rate; the FN value for WWF$_{us}$ was steadily minimal ($65 \pm 3$ s) after 12 h, for WWF$_{contr}$ – after 16 h. US treatment provides rapid penetration of moisture to the embryo and endosperm [29].

The nature of the decrease in the FN value for wheat grain demonstrates an inverse curvilinear relationship between germination time and the FN value. This is consistent with studies by Singh et al. who found a similar decrease in FN values during germination [30].

Changes in the FN values during germination can be described by a second-order polynomial equation with high determination coefficients, especially for WWF$_{contr}$ samples. The use of polynomial curves will help to determine the FN of wheat grains and control the duration of germinating for processing (baking industry, technology for the production of biologically active substances, etc.).

We have determined the germination time of *Triticum aestivum* L. wheat grain for whole-wheat flour technology (Fig. 5). For WWF$_{contr}$, it is no more than 18 h, for WWF$_{us}$ – 14 h.

The use of ultrasonic influence allows us to reduce the term of the germination process by 4 h and control this process. The mechanism of ultrasonic influence is described in the works of several authors [14]. The researchers prove that ultrasonic vibrations cause formation, growth and intense destruction of microbubbles in the treated liquid medium, where acoustic cavitation is observed. This phenomenon implies alternate compressing and stretching of the molecular structure of the medium. During each phase of stretching (rarefaction) phase, the liquid medium can literally rupture, forming tiny cavities (microbubbles). During the exposure cycle, these cavities can collapse, releasing large amounts of energy in the immediate proximity of the microbubbles.

Bubbles collapse near the surface asymmetrically and fluid flow is impeded by the hard surfaces of the wheat grain in the hydromodule. A jet of water falls on the surface of the wheat grain, thus collapsing the cavitation bubble. Such a water jet can (i) damage the shell walls of the grain, (ii) increase water absorption by the shell parts, and (iii) increase heat and mass transfer from the surface.

Note that the mechanical and chemical effects of collapse work in two different areas: (i) within the bubble, which can be seen as a high-pressure and high-temperature microreactor, and (ii) in the immediate vicinity of the bubble, where the shock wave generated by collapse creates enormous shear forces that alter the physical and chemical properties of water. The shock waves of the cavitation field break hydrogen bonds in the water structure [14,31]. High adsorption activity of hydroxyl ions due to ultrasonic influence accelerates soaking of the wheat grain surface.

The obtained results agree with the data of the researchers Ding, Hou et al. [23], who found a change in the surface microstructure of red rice kernels and microcracks in their shells. Miano, Pereira et al. [32] in their studies also describe similar effects, which can accelerate the process of hydration of bean cultures when germinating by 25%.

Then, we have studied the effect of ultrasonic treatment on the particle size of whole-wheat flour synthesis of GABA ($\gamma$-aminobutyric acid), flavonoids and a change in the total AOA.

![Fig. 4. Changes in falling-number value (FN) (in terms of 14% humidity): whole-wheat flour made from germinated wheat at 22 $\pm 2^\circ$C during 16 h at a relative humidity of 95 $\pm 3\%$. *Abbreviations: falling number, FN; whole-wheat flour made from germinated wheat (WWFcontr); whole-wheat flour made from germinated wheat exposed to US treatment (WWFus).](image-url)
4.3. Granulometric composition and microstructural characteristics of whole-wheat flour

The main parameter of suitability in bread technology is obtaining flour with particles of a fixed size. The processes that occur in the grain during germination affect the strength properties of the grains; therefore, special conditions are required for grinding. It was not recommended in some studies to grind the germinated grain with classical grinding, since high plasticity of the grains reduces the yield of flour and increases the ash content in the flour [33]. According to Ariyama and Khan [34], germination significantly reduces the yield of flour (by about 6% after 40 h of wheat germinating). Biologically active compounds in the grain are mainly located in the shell parts. Therefore, the production of flour by milling for this type of grain raw materials is most preferable. For dry grinding, the moisture content of the germinated grain should be no higher than 14% [35]. Grinding should lead to determining the particle size distribution which is important from a technological point of view, since it affects the properties of flour and subsequent processing steps [36]. In studies such parameters as the particle size distribution (Fig. 6) and the average-weighted particle size (d) were used to characterize the granulometric composition of whole-wheat flour.

The results showed that the ground product obtained from germinated wheat grain (WWFcontr and WWFus) contained a higher proportion of large particles (more than 104 ± 6 μm) and a low proportion of small particles (4.5 ± 1.2–104 ± 4.5 μm). The average-weighted particle size of germinated samples was WWFcontr – 176 ± 15 μm and WWFus – 170 ± 15 μm.

The grinding process, which depends on the degree of adhesion between the starch granules and the protein matrix, is significant for flour produced from germinated wheat grains [37]. The results of scanning electron microscopy (SEM) (Fig. 7) characterize the internal packing of particles, their distribution and aggregation.

SEM micrographs indicate large compactly packed discrete particles [38] (protein matrix aggregates) with undamaged swollen starch grains (A) in whole-ground WWFus flour. In addition, we can see a large amount of undamaged starch grains (B) and protein matrix (C). In the WWFcontr whole-wheat flour sample, we can find large aggregates of the protein matrix (A) in large quantities with non-swollen starch grains and a dense protein matrix (C); occasionally, large starch grains (B) are found. Moreover, in whole-wheat flour, both WWFcontr and WWFus, we can find separate large shell particles of grain (D) with individual inclusions of starch grains. An additional decrease in grain hardness resultant from US exposure led to the formation of particles of a more uniform size, rounded shape, with a minimum number of damaged starch grains.

4.4. Technological characteristics of whole-wheat flour

For the technology of products based on whole-wheat flour, important indicators of its suitability are physical and chemical characteristics (Table 1), based on the quantity and quality of nutrients, especially gluten complex. The formation of a protein network in dough making is due to the presence of hydrophobic interactions between nonpolar groups of protein molecules, the occurrence of redox reactions due to the oxidation of sulfhydryl groups by oxygen with the formation of disulfide bonds, including cross between individual protein polypeptide chains, as well as hydrogen bonds (see Table 2).

In all whole-flour samples, the moisture content was 13.5 ± 0.8% with almost constant Ash (% d.b.). The protein content in WWFcontr and WWFus is higher than GNG by 18.9% and 19.8%, respectively.
values of the gluten index and the content of wet gluten in WWF

Contr and WWF us flour was significantly different \((p \leq 0.05)\) from GNG. On one hand, changes in the gluten index can be due to the relaxing effect of proteolytic enzymes that get activated during germination. On the other hand, they can occur due to the formation of phenolic compounds capable of binding sulfides available for the formation of disulfide bridges. When the structure of gluten is formed, protein oxidation and gluten strengthening can also occur \([39,40]\). This process compensates for the effects of proteolytic enzymes.

US intensification of the germinating process reduces the amount of starch by 18.7\%. Such changes can have a negative effect on the strength of the porous structure of the crumb after baking. SEM micrographs of the whole-wheat flour dough (Fig. 8) prove a change in the structure. Therefore, dosage adjustment of the component is necessary.

In the GNG dough we can visualize starch grains of round or elliptic form of small and medium size (B), which are fixed in a moderately developed protein matrix (C). In model WWF contr and WWF us dough samples, protein granules and large starch grains (A) represent a single, excessively liquefied amorphous structure.

According to the data obtained, we believe that the usage of WWF us obtained in the production of bakery products should be balanced. These structural changes during dosed application will make it possible to obtain a more elastic and extensible dough, which will increase the porosity and specific volume of final products.

4.5. Synthesis of GABA in whole-wheat flour from germinated wheat

An important substance that is accumulated during germinating is GABA, a protein free amino acid, which is mainly formed as a result of \(\gamma\)-decarboxylation of 1-glutamic acid, which is catalyzed by the enzyme glutamate decarboxylase \([41]\). The effect of GABA synthesis activation in germinated wheat has been found and described \([42,43]\).

An HPLC analysis showed (Fig. 9) that each wheat grain sample contained GABA (Fig. 7), but the GABA content in WWF us was significantly higher (18.9 mg/100 g) than in WWF contr (6.3 mg/100 g) and in non-germinated grain (2.6 mg/100 g).

Junzhou Ding, Gary G. Hou, Boris V. Nemzer and other authors \([32]\) found that the use of ultrasound can activate GABA formation during germination of cereal crops. Since the stress provoked by ultrasound activates endogenous enzymes (in particular, glutamate decarboxylase), which leads to sharp increase in GABA in germinated grains.

Baranzelli J., Krügel D.H., Colussi R. et al. established that increase in GABA during wheat germination under abiotic stress produced by ultrasound is explained by the increased activity of glutamate decarboxylase, which decarboxylates L-glutamate, activates glutamate decarboxylase enzyme and releases GABA \([9]\). Junzhou Ding and his colleagues \([21]\) name this process a short pathway of GABA synthesis or a GABA stunt.

According to the results of their studies, Junzhou Ding, Gary G. Hou, Shanbai Xiong and their colleagues \([32]\) determined that ultrasound treatment increased the content of succinic acid with simultaneous

Fig. 7. Scanning electron micrographs of whole-wheat flour made from germinated wheat: A – protein matrix aggregates, B – large starch grains, C – protein matrix, D – shell particles of grain, magnification 250×, 1500×, 2000×.

![Table 1](image)
increase in metabolites associated with GABA shunt, such as glutamic acid, alanine and tricarboxylic acid, in the grain after ultrasound treatment. This suggests that increased polyamine degradation and inhibition of glutamate transamination may contribute to the accumulation of GABA in the grain during ultrasonic treatment. Thus, ultrasound exposure (as a stress) increases the energy metabolism of wheat grain germination. It leads to increased GABA accumulation by enhancing the activity of glutamate decarboxylase and providing more L-glutamate. Whereas traditional methods of germination do not allow activating the above mentioned processes and obtaining high values of GABA in the final product [42]. The obtained results showed a potential for the production of bakery products enriched with GABA and other functional components.

4.6. AOA of whole-wheat flour

Germinating leads to the activation of enzymatic processes. These processes are aimed at the release of phytochemicals from the embryo, endosperm and shell parts, including flavonoids which determine antioxidant activity. The US intensification of the germination process

| Initial stage | Three hours later |
|---------------|------------------|
| GNG           |                  |
| WWFcontr      |                  |
| WWFus         |                  |
| Control       |                  |

Table 2
Micrographs of neuroblastoma cells.

Fig. 8. Scanning electron micrographs of whole-wheat flour dough: A – large starch grains, B – starch grains of small and medium size, C – protein matrix, magnification 1000×.

Model dough sample made from GNG  Model dough sample made from WWFcontr  Model dough sample made from WWFus
affected (Fig. 10) the value of the total antioxidant activity, growth for WWFus was 73%, the number of flavonoids increased by 160%. A similar dynamics was noted during the germination of Canadian wheat [4].

Researchers of the germination process of Romaine lettuce, red rice [23] and other cereal crops established that ultrasonic exposure can act as an abiotic stress factor for plants. The studies describe that ultrasonic exposure triggers the protective response of the plant organism and stimulates the production of secondary metabolites such as phenolic compounds, thus enhancing the antioxidant activity of wheat grain during germination.

The utility assessment of the components of whole-wheat flour from germinated wheat grains for consumers was performed on the cell model of an undifferentiated human neuroblastoma SH-SY5Y. The results of measuring the dye fluorescence intensity proportional to the amount of AOF are shown in Fig. 11. Fluorescence intensity with PMA was taken as a standard unit.

The data given in Fig. 11 show that the WWFus sample is the most active in blocking (AOF) 0.75 with respect to the PMA control, which is generally expected and consistent with previous results of our AOA studies (DPPH). In the WWFcontr sample antioxidant activity was lower (fluorescence intensity 0.84 with respect to the PMA control).

Micrographs visualizing changes in the fluorescence of cell cultures of undifferentiated neuroblastoma during the study of inhibition of AOF flour samples demonstrate some degree of antioxidant activity.

According to the data obtained, the fluorescence intensity at the end of the study was minimal for the WWFus sample, which corresponds to the data in Fig. 11.

Thus, studies of antioxidant activity using a neuroblastoma cell model show an increase in the antioxidant properties of wheat during germination. The growth of the antioxidant activity of the germinated grain samples in relation to non-germinated was 5.6% and 15.7% for WWFus and WWFcontr, respectively. The AOA gets minimal values in traditional germination methods (WWFcontr) [45] due to the lack of an abiotic stress factor and the absence of an organism response.

5. Conclusions

The ultrasonic treatment can be one of the effective factors...
stimulating the intensity of grain germination in the production of healthy products. If we take into account the proposed modes of a controlled germinating process exposed to ultrasound, it will be possible to provide an effective and fast way to increase GABA and AOA in grain-based products. We plan to continue the research in order to study the synthesis of GABA and AOA in WWF during baking processes, as well as to assess the utility of WWF in final products for increasing their nutrient value.
