(Dated: May 15, 2012)

We use the Bogoliubov-de Gennes formalism and study the ground-state phases of trapped spin-orbit coupled Fermi gases in two dimensions. Our main finding is that the presence of a symmetric (Rashba-type) spin-orbit coupling spontaneously induces counterflowing mass currents in the vicinity of the trap edge, i.e. ↑ and ↓ particles circulate in opposite directions with equal speed. These currents flow even in noninteracting systems, but their strength decreases toward the molecular BEC limit, which can be achieved either by increasing the spin-orbit coupling or the interaction strength. These currents are also quite robust against the effects of asymmetric spin-orbit couplings in \(x\) and \(y\) directions, gradually reducing to zero as the spin-orbit coupling becomes one dimensional. We compare our results with those of chiral \(p\)-wave superfluids/superconductors.

I. INTRODUCTION

The controversy over the expectation value of the intrinsic ground-state angular momentum of the \(A\)-phase of superfluid \(^3\)He in a given container has a long history, and it has not yet attained a universally agreed resolution \([1]\). For \(N\) weakly-interacting particles, theoretical predictions for the BCS ground state vary orders of magnitude from \(N|\Delta|\hbar/(2\varepsilon_F)\) to \(N\hbar/2\), where \(|\Delta|\) is the amplitude of the order parameter, i.e. pairing energy, and \(\varepsilon_F\) is the Fermi energy. At a first glance, the former expectation, which is based on the observation that pairing affects not all but only a small fraction \((|\Delta|/\varepsilon_F)N\) of fermions, seems more intuitive. However, this subject has recently regained interest in condensed-matter and atomic and molecular physics communities due to its relevance to the possible \(p_\perp+i p_\parallel\)-superconducting phase of \(\text{Sr}_2\text{RuO}_4\) \([2]\) and atomic chiral \(p\)-wave superfluids \([3]\), respectively, supporting for the latter expectation \([4,5]\). On one hand, these recent results seem intuitive at least in the strong fermion attraction limit of tightly-bound \(p\)-wave Cooper molecules, where all of the molecules can undergo BEC at zero temperature with each molecule having a microscopic angular momentum \(\hbar\). On the other hand, they seem counterintuitive in the weak fermion attraction limit of loosely bound and largely overlapping \(p\)-wave Cooper pairs, since these results imply that the angular momentum in the BCS ground state is macroscopically different from its vanishing value in the normal ground state, when the pairing energy becomes arbitrarily small. While this controversy still awaits for an experimental resolution, here we propose an alternative atomic system where the microscopic angular momentum of Cooper pairs can also give rise to a macroscopic one. With their unique advantages over the condensed-matter systems, it is plausible that the macroscopic angular momentum of this alternative system may be observed for the first time with cold atoms, and that this would also shed some light on the \(^3\)He controversy for which the basic mechanism is found to be similar.

Cold atom systems have already proved to be versatile in simulating various many-body problems. For instance, one of the major achievements with atomic Fermi gases in the past decade is the unprecedented realization of the BCS-BEC crossover \([6]\), where the ground state of the system can be continuously tuned from the BCS to the BEC limit as a function of increasing fermion attraction with the turn of a knob. The main difference between the BCS-BEC crossover and the BCS theory is that the Cooper pairing is allowed not only for fermions with energies close to the Fermi energy but also for all pairs with appropriate momenta \([1,6]\). Having established the basic tools, it is arguable that one of the most promising research directions to pursue with cold Fermi gases is the artificial spin-orbit gauge fields. Such a field has already been realized with cold Bose gases \([7,8]\) using a novel technique based on spatially-dependent optical coupling between internal states of the atoms, and the same technique is equally applicable for neutral fermionic atoms. In fact, we have recently learned that the first generation of quantum degenerate spin-orbit coupled Fermi gases has recently been created with \(^{40}\)K atoms \([9]\).

This immediate possibility of creating a spin-orbit coupled Fermi gas has already received tremendous theoretical interest in condensed-matter and atomic physics communities, exploring a number of exotic superfluid phases with balanced or imbalanced populations, at zero or finite temperatures, in two or three dimensions, etc. \([10–23]\). Motivated by these recent advances, here we study ground-state and finite-temperature phases of trapped spin-orbit coupled Fermi gases, and our main results are as follows. We find that the presence of a spin-orbit coupling (SOC) spontaneously induces counterflowing ↑ and ↓ mass currents in the vicinity of the trap edge \([24]\). We show that these currents flow even in noninteracting systems, and that they are quite robust against the effects of asymmetric SOC in \(x\) and \(y\) directions, gradually reducing to zero as the SOC becomes one dimensional. However, their strength decreases toward the molecular BEC limit, which can be achieved either by increasing the SOC or the interaction strength. We argue that the origin of spontaneously induced counterflowing mass currents in spin-orbit coupled Fermi gases can be understood via a direct correspondence with the chiral \(p\)-wave superfluids/superconductors, however,
with some fundamental differences in between.

The rest of the paper is organized as follows. In Sec. [II] first we introduce the mean-field Hamiltonian that is used to describe the spin-orbit coupled Fermi gases on optical lattices, and then use the Bogoliubov-de Gennes (BdG) formalism to obtain the generalized self-consistency equations for the number of fermions, superfluid order parameter, and strength of circulating mass currents. The numerical solutions of this formalism are presented in Sec. [III] which is followed by a brief discussion on their experimental realization in Sec. [IV]. We summarize our main findings in [V].

II. THEORETICAL BACKGROUND

In this paper, we consider a harmonically trapped two-dimensional optical lattice in the presence of a non-Abelian gauge potential. In addition to the usual spin-conserving hopping terms, the main effect of such a gauge potential is the appearance of an additional spin-flipping hopping term in the single-particle kinetic energy term as discussed next.

A. Hamiltonian

Spin-orbit coupled Fermi gases on optical lattices can be described by the grand-canonical mean-field Hamiltonian,

\[
H = -t \sum_{i,\ell} \left( C_{i+\ell}^\dagger \phi_{i+\ell,\sigma} C_i + H.c. \right) - \sum_i (\mu_\sigma + V_{\sigma i}^H - V_{\sigma i}^T) C_{i\sigma}^\dagger C_{i\sigma} + \sum_i \left( \Delta_0 c_{i\sigma}^\dagger c_{i\bar{\sigma}} + \Delta_0^* c_{i\bar{\sigma}}^\dagger c_{i\sigma} \right),
\]

where the operator \( c_{i\sigma}^\dagger \) (\( c_{i\sigma} \)) creates (annihilates) a pseudospin \( \sigma = \{\uparrow, \downarrow\} \) fermion at lattice site \( i \), the spinor \( C_i = (c_{i\uparrow}, c_{i\downarrow}) \) denotes the fermion operators collectively, \( \hat{e} = \{\hat{x}, \hat{y}\} \) allows only nearest-neighbor hopping, and \( H.c. \) is the Hermitian conjugate. For a generic gauge field \( A = (\alpha \sigma_y, -\beta \sigma_x) \), where \( \sigma_x, \sigma_y, \sigma_z \) are the Pauli matrices and \( \{\alpha, \beta\} \geq 0 \) are independent parameters characterizing both the strength and the symmetry of the spin-orbit coupling, the \( \uparrow \) and \( \downarrow \) fermions gain \( \phi_{i+\ell,\sigma} = e^{-i\alpha \sigma_y} \) phase factors for hopping in the positive \( x \) direction and \( \phi_{i+\hat{y},\sigma} = e^{i\beta \sigma_x} \) phase factors for hopping in the positive \( y \) direction. Note that the spin-conserving and spin-flipping hopping terms are proportional, respectively, to \( \cos \alpha \) and \( \sin \alpha \) in the \( x \) direction, and to \( \cos \beta \) and \( \sin \beta \) in the \( y \) direction. The off-diagonal coupling \( \Delta_0 \) is the mean-field superfluid order parameter to be specified below, and \( V_{\sigma i}^H = gn_{-\sigma i} \) is the Hartree term where \( g \geq 0 \) is the strength of the onsite attractive interaction and \( n_{\sigma i} \) is the filling of \( \sigma \) fermions at site \( i \). Here, \( (-\uparrow) = \downarrow \) and vice versa. We introduce \( \sigma \)-dependent chemical potentials \( \mu_{\sigma} \) to fix the number of \( \sigma \) fermions independently, but we assume both \( \uparrow \) and \( \downarrow \) fermions feel the same trapping potential \( V_{\sigma i}^T = V_0 r_{\sigma i}^2 / 2 \), where the distance \( r_{\sigma i} \) is measured from the center in our \( L \times L \) lattice. Next, we solve this Hamiltonian via BdG formalism.

B. Bogoliubov-de Gennes formalism

The BdG equations are obtained by diagonalizing the quadratic Hamiltonian given above via a generalized Bogoliubov-Valatin transformation, leading to a \( 4L^2 \times 4L^2 \) matrix-eigenvalue problem.

\[
\sum_j \left( \begin{array}{cccc}
T_{\uparrow \uparrow} & T_{\uparrow \downarrow} & 0 & \Delta \\
T_{\downarrow \uparrow} & T_{\downarrow \downarrow} & -\Delta & 0 \\
0 & -\Delta^* & -T_{\uparrow \uparrow} & T_{\downarrow \uparrow} \\
\Delta^* & 0 & -T_{\downarrow \uparrow} & -T_{\downarrow \downarrow}
\end{array} \right) \begin{pmatrix} u_{nj}^\uparrow \\ u_{nj}^\downarrow \\ v_{nj}^\uparrow \\ v_{nj}^\downarrow \end{pmatrix} = \varepsilon_n \begin{pmatrix} u_{ni}^\uparrow \\ u_{ni}^\downarrow \\ v_{ni}^\uparrow \\ v_{ni}^\downarrow \end{pmatrix},
\]

where \( u_{ni}^\sigma \) and \( v_{ni}^\sigma \) are the components of the \( n \)th quasiparticle wave function at site \( i \), and \( \varepsilon_n \geq 0 \) is the corresponding energy eigenvalue. While the off-diagonal couplings are \( \Delta_{ij} = \Delta_{\sigma j} \delta_{ij} \) diagonal in site indices since we consider onsite interactions only, the nearest-neighbor hopping and onsite energy terms can be written compactly as \( T_{2\sigma i j}^\sigma = -t\delta_{ij} - (\mu_\sigma + V_{\sigma i}^H - V_{\sigma j}^T) \delta_{ij} \delta_{\sigma \sigma'}, \) where \( \delta_{ij} \) is the Kronecker delta. Here, the non-vanishing nearest-neighbor hopping elements \( t_{\sigma i j}^{\uparrow \downarrow} = t_{\sigma i j}^{\downarrow \uparrow} = -t \sin \alpha \) for the positive \( x \) direction, and \( t_{\sigma i j}^{\uparrow \downarrow} = t \cos \beta \) and \( t_{\sigma i j}^{\downarrow \uparrow} = t \sin \beta \) for the positive \( y \) direction. Note that the hopping in the negative \( x \) and \( y \) directions are simply the Hermitian conjugates.

Equation (2) needs to be solved simultaneously with the order parameter \( \Delta_i = g(c_{i\uparrow} c_{i\downarrow}) \) and number \( n_{\sigma i} = \langle c_{i\sigma}^\dagger c_{i\sigma} \rangle \) equations for a self-consistent set of \( \Delta_i \) and \( n_{\sigma i} \) solutions. Here, \( \langle \cdot \rangle \) is a thermal average. Using the Bogoliubov-Valatin transformation, we obtain

\[
\Delta_i = g \sum_n \left[ u_{ni}^\uparrow (v_{ni}^\uparrow)^* f(-\varepsilon_n) + u_{ni}^\downarrow (v_{ni}^\downarrow)^* f(\varepsilon_n) \right],
\]

\[
n_{\sigma i} = \sum_n \left[ |u_{ni}^\sigma|^2 f(\varepsilon_n) + |v_{ni}^\sigma|^2 f(-\varepsilon_n) \right],
\]

where \( f(x) = 1/(e^{x/T} + 1) \) is the Fermi-Dirac distribution function and \( T \) is the temperature. Here, we set the Boltzmann constant \( k_B \) to unity. Note that \( 0 \leq n_{\sigma i} \leq 1 \) is the number of \( \sigma \) fermions at site \( i \) (number filling) in such a way that \( N_{\sigma} = \sum_i n_{\sigma i} \) gives the total number of \( \sigma \) fermions. Equations (2)-(4) correspond to the generalization of the BdG equations [25] to the case of spin-orbit coupled Fermi gases on optical lattices.

C. Circulating mass currents

Once we obtain the self-consistent solutions for the quasiparticle wave functions and the corresponding energy spectrum, it is straightforward to calculate any of the desired observables. For instance, in this paper we are interested in the
quantum mechanical probability-current (mass- or particle-current) of \( \sigma \) fermions at site \( i \) defined by \( J_{\sigma i} = \sum_{\alpha} \hat{J}_{\sigma \alpha}^i \), where \( \hat{J}_{\sigma \alpha}^i = -i \tau_{\sigma \alpha}^{\dagger} \hat{c}_{\alpha, i + \hat{e}} \hat{c}_{\alpha, i} + H.c. \) is the \( \alpha \)th component. Using the Bogoliubov-Valatin transformation, we obtain

\[
J_{\sigma i} = -i \tau_{\sigma \alpha}^{\dagger} \sum_n \left[ (u_{ni})^* u_{n, i + \hat{e}} f(\varepsilon_n) + (v_{ni})^* v_{n, i + \hat{e}} f(-\varepsilon_n) - H.c. \right],
\]

where we set the lattice spacing and \( \hbar \) to unity. In our two-dimensional system, we expect mass currents to circulate around the central site, so that \( \mathbf{J}_{\sigma i} = J_{\sigma i} \hat{\theta} \), where \( \theta \) is the azimuthal angle. In addition, the local angular-momentum associated with such a circulating mass current is in the \( \mathbf{z} \) direction, and its magnitude at a particular site \( i \) is simply related to the local mass current by \( J_{\sigma i} = x_i J_{\sigma x}^i - y_i J_{\sigma y}^i \), where \( x_i \) and \( y_i \) are the coordinates of site \( i \) with respect to the center, i.e. minimum of the trapping potential. In this paper, we are interested in the total absolute angular momentum per \( \sigma \) particle which is given by \( J_{\sigma} = (1/N_\sigma) \sum_i r_i |J_{\sigma i}| \).

Having established the BdG formalism, now we are ready to present our numerical solutions for the ground-state and finite-temperature phases, which are obtained by solving Eqs. (2-4) in a self-consistent manner.

### III. NUMERICAL RESULTS

Our numerical calculations are performed on a two-dimensional square lattice with \( L = 48 \) lattice sites in each direction. We take \( V_0 \approx 0.014 t \) as the strength of the trapping potential, and discuss both symmetric (\( \alpha = \beta \)) and asymmetric (\( \alpha \neq \beta \)) SOC fields. Since we are mainly interested in the low-filling population-balanced systems, we set \( N_\uparrow = N_\downarrow = 125 \), and study the resultant phases as a function of \( g, \alpha \) and \( \beta \). However, we briefly comment on the effects of high filling and population imbalance on the ground-state phases toward the end of this section.

In Fig. 1, we show the strength of the \( \uparrow \) mass current \( J_{\uparrow i} \) at zero temperature \( (T = 0) \) for noninteracting \( (g = 0) \) systems with symmetric and asymmetric SOC, where we set \( \alpha = \pi/4 \) and vary \( \beta \) parameter. We use Fig. 1(a) as our reference data in all of our discussions below. First of all, the coarse-grained data near the trap center is a finite-size lattice effect and it does not affect our main findings. In addition, due to the time-reversal symmetry, \( J_{\uparrow i} \) has exactly the opposite circulation for population-balanced systems and this current is not shown throughout this paper. As \( \beta \) decreases from the symmetric case with \( \beta = \pi/4 \) to \( \beta = 0 \), the asymmetry between \( x \) and \( y \) directions increase in such a way that the spin-flipping hopping gradually decreases to zero in the \( y \) direction, and the SOC field eventually becomes purely one dimensional in the \( x \) direction. We find that the mass current flows as long as the SOC field has both \( x \) and \( y \) components, and its strength decreases gradually as a function of increasing the asymmetry of SOC fields. Note that since the asymmetric SOC breaks the \( C_4 \) symmetry of the square lattice, the resultant mass currents also have reduced symmetry in Figs. 1(b) and (c). In addition, we see that the gas expands a little bit with increasing asymmetry, which is due to the decrease in density of single-particle states.

In Fig. 2, we show the mass current \( J_{\uparrow i}^\alpha \) and filling \( n_{\uparrow i} \) of \( \uparrow \) fermions at \( T = 0 \) for noninteracting systems with varying symmetric SOC strengths \( \alpha = \beta \). We find that \( J_{\uparrow i} \) first increases and then decreases as \( \alpha = \beta \) is increased from 0 to \( \pi/2 \). It is expected that the strength of the mass current rapidly increases as a function of increasing spin-flipping hopping with respect to the spin-conserving ones, since the presence of a nonzero SOC is what allowed the mass current to form in the first place. However, as the SOC terms dominate, the chemical potential gradually drops below the band minimum, and then the system gradually crosses over to the
molecular BEC side. We note that in contrast to the no-SOC case where the formation of a two-body bound state between \(\uparrow\) and \(\downarrow\) fermions requires a finite interaction threshold in a two-dimensional lattice, here it can form even for arbitrarily small interactions simply by increasing the SOC, due to the increased single-particle density of states. Therefore, it is expected that the rapid increase in the strength of the mass current is followed by a gradual decrease at larger SOC, and that the mass current eventually vanishes at sufficiently large SOC.

In addition, we see that the gas shrinks with increasing SOC, which is again due to the increased density of states. Note that the ratio between the trapping potential and the effective hopping terms also increases as \(\alpha = \beta\) increases from 0 to \(\pi/2\).

We also calculate the absolute angular momentum per particle \(L^z_\sigma\) and find approximately 0.53, 0.56 and 0.38 (in units of \(\hbar\)), when \(\alpha = \beta\) is set to \(\pi/4\), 5\(\pi/16\) and 7\(\pi/16\), respectively.

In Fig. 4, we show the mass current \(J^\sigma_{\uparrow}\) and filling \(n_{\uparrow}\) of \(\uparrow\) fermions for noninteracting systems with varying temperature \(T\), where we set symmetric (\(\alpha = \beta = \pi/4\)) SOC. Since finite temperature excites more and more particles to higher oscillator states as a function of increasing \(T\), and this naturally leads to an increase in the system size, and decrease in the strength of the mass currents. This is clearly seen in the figure, where the peak value of \(J^\sigma_{\uparrow}\) reduces approximately to half of its \(T = 0\) value when \(T \approx 0.14t\), but with a larger width. We calculate the absolute angular momentum per particle \(L^z_\sigma\) and find approximately 0.53, 0.33 and 0.16 (in units of \(\hbar\)), when \(T\) is set to 0, 0.14\(t\) and 0.35\(t\), respectively. Therefore, \(L^z_\sigma\) decreases significantly from its ground-state value \(\approx 0.5\) as the temperature increases.

So far we only discussed population-balanced systems with a low filling at the trap center, i.e. \(n_{\sigma i} \lesssim 0.4\), and here we briefly comment on the effects of high filling and population imbalance on the ground-state phases [25]. First of all, due to the particle-hole symmetry of the Hamiltonian around \(n_{\sigma i} = 0.5\), in addition to the mass-current peak circulating in the vicinity of the trap edge, an additional peak that is circulating mostly near the trap center is induced when the trap...
center is close to a band insulator, i.e. $n_{\uparrow \downarrow} \approx 1$. Therefore, mass currents show a double-ring structure in high-filling lattice systems. Second, the strengths of mass currents are quite robust against the effects of imbalanced populations. For instance, when the total number of ↓ fermions is reduced from $N_\downarrow = 125$ in Fig. 1(a) to $N_\downarrow = 20$ while keeping $N_\uparrow = 125$ fixed, so that $n_\uparrow \approx 0.3$ and $n_\downarrow \approx 0.05$ at the trap center, the maximum currents $J_\uparrow \gtrsim J_\downarrow \approx 5 \times 10^{-3} E_\text{F}$ occur about the same radial distance as the population-balanced case shown in Fig. 1(a).

IV. DISCUSSION

Having established the qualitative behavior of spontaneously induced counterflowing mass currents in spin-orbit coupled Fermi gases, next we argue that the origin of these currents can be understood via a direct correspondence with the chiral $p$-wave superfluids/superconductors.

A. Correspondence with chiral $p$-wave systems

The origin of spontaneously induced counterflowing mass currents near the trap edge can be understood via a direct correspondence with the $p_x + ip_y$ superfluids/superconductors, e.g. A phase of liquid $^3$He, for which it is known that a spontaneous mass current also flows near the boundary [4, 5]. In these $p$-wave systems, the mass current and hence the macroscopic angular momentum is associated with the chirality of Cooper pairs. The chirality can be most easily seen by noting that the chiral $p$-wave order parameter $\Delta_k \propto (\pm \vec{\sigma} \cdot \vec{r}) \cdot \vec{k}$, where $\vec{k}$ is the relative momentum of a Cooper pair, is an eigenfunction of the orbital angular momentum with eigenvalue $\pm \hbar$. This mechanism explains our findings since it can be shown that the order parameter of spin-orbit coupled Fermi gases with Rashba-type SOC and $s$-wave contact interactions has chiral $p$-wave symmetry. To see this one needs to transform the Hamiltonian to the helicity basis, i.e. the pseudospin is no longer a good quantum number in the presence of a SOC, and the spin direction is either parallel or anti-parallel to the direction of in-plane momentum in the $\pm$ helicity basis. In the helicity-basis representation, it becomes clear that only intraband Cooper pairing occurs between fermions with same helicity, and that the order parameter for $\pm$ helicity pairing has $p_x \pm ip_y$ symmetry [12].

Although the basic mechanism in chiral $p$-wave systems and spin-orbit coupled Fermi gases share some similarities with respect to spontaneously induced edge currents, they also differ in fundamental ways. For instance, in contrast to the chiral $p$-wave systems where the formation of Cooper pairs and hence the mass current requires an interacting system, in spin-orbit coupled Fermi gases currents flow even in the absence of interactions. In addition, the chiral $p$-wave systems belong to the topological class of integer quantum Hall systems, and since these systems both break time-reversal symmetry, they exhibit spontaneous edge currents circulating along a particular direction. However, spin-orbit coupled Fermi gases preserve time-reversal symmetry just like quantum spin Hall systems, and therefore, they both exhibit spontaneously induced counterflowing $\uparrow$ and $\downarrow$ edge currents. Next, we comment on the experimental realization of spontaneously induced edge currents in atomic systems.

B. Experimental realization

In comparison to bulk (center) effects, there is no doubt that the edge effects are more difficult to observe in trapped atomic systems. This is because as the local density decreases from the central region to the edges, it gets harder to probe local properties. In addition, the local critical superfluid temperature eventually drops below the temperature of the system near the edges, and the superfluidity is also lost starting from the edges inwards. One way to partially overcome such problems could be to load the optical lattice potential with higher particle fillings such that the trap center is close to a band insulator, i.e. unit filling. In this case, an additional mass-current peak circulates mostly near the trap center (see above), and such a local current could be easier to probe with current experimental capabilities.

The measurement of the angular momentum of rotating atomic systems have so far only been achieved indirectly, by observing the shift of the radial quadrupole modes. While this technique was initially used for rotating atomic BECs [26, 27], it has recently been applied to the rotating fermionic superfluids in the BCS-BEC crossover [28]. We believe a similar technique could be used for measuring the intrinsic angular momentum of spin-orbit coupled Fermi gases, which may provide an indirect evidence for counterflowing mass currents. In addition, we note that a realistic scheme has recently been proposed to detect topological edge states in an optical lattice under a synthetic magnetic field [29]. This proposal is based on a generalization of Bragg spectroscopy that is sensitive to angular momentum.

V. CONCLUSIONS

To conclude, we showed that the presence of a Rashba-type SOC spontaneously induces counterflowing $\uparrow$ and $\downarrow$ mass currents. While these currents have a single peak that is circulating mostly near the trap edge in low-filling lattice systems, an additional peak that is circulating mostly near the trap center is also induced in high-filling lattice systems, exhibiting a double-ring structure. We note that our results for the low-filling lattice systems are directly applicable to the dilute systems (without the optical lattice potential), for which we expect qualitatively similar behavior. These currents flow even in noninteracting systems, and they are quite robust against the effects of imbalanced populations and/or asymmetric SOC in $x$ and $y$ directions. However, their strength decreases toward the molecular BEC limit, which can be achieved either by increasing the SOC or the interaction strength. We argued that the origin of spontaneously induced counterflowing mass currents in spin-orbit coupled Fermi gases can be understood
via a direct correspondence with the chiral $p$-wave superfluids/superconductors, however, with some fundamental differences in between.
