Lead(II) chloride ionic liquids and organic/inorganic hybrid materials - a study of chloroplumbate(II) speciation

Coleman, F., Feng, G., Murphy, R. W., Nockemann, P., Seddon, K. R., & Swadzba-Kwasny, M. (2013). Lead(II) chloride ionic liquids and organic/inorganic hybrid materials - a study of chloroplumbate(II) speciation. Dalton Transactions, 42(14), 5025-5035. https://doi.org/10.1039/c3dt32742f
Lead(II) chloride ionic liquids and organic/inorganic hybrid materials – a study of chloroplumbate(II) speciation†

Fergal Coleman, Guo Feng, Richard W. Murphy, Peter Nockemann, Kenneth R. Seddon and Małgorzata Swadźba-Kwaśny*

A range of chloroplumbate(II) organic salts, based on the two cations, 1-ethyl-3-methylimidazolium and trihexyl(tetradecyl)phosphonium, was prepared by ionothermal synthesis. Depending on the structure of the organic cation and on the molar ratio of PbCl2 in the product, 1/PbCl2, the salts were room-temperature ionic liquids or crystalline organic/inorganic hybrid materials. The solids were studied using Raman spectroscopy; the crystal structure of [C2mim]{PbCl3} was determined and shown to contain 1D infinite chloroplumbate(II) strands formed by edge-sharing tetragonal pyramids of pentacoordinate (PbCl5) units. The liquids were analysed using 207Pb NMR and Raman spectroscopies, as well as viscometry. Phase diagrams were constructed based on differential scanning calorimetry (DSC) measurements. Discrete anions: [PbCl4]2– and [PbCl3]–, were detected in the liquid state. The trichloroplumbate(II) anion was shown to have a flexible structure due to the presence of a stereochemically-active lone pair. The relationship between the liquid phase anionic speciation and the structure of the corresponding crystalline products of ionothermal syntheses was discussed, and the data were compared with analogous tin(II) systems.

Introduction

Salts comprising of organic cations and halometallate anions are of interest in several fields of material sciences. For example, crystalline chloroplumbate(n) systems may be considered as organic/inorganic hybrid compounds, with a tendency to form 2D perovskites and low-dimensional crystalline materials with electro-optic characteristics (photoluminescence, electroluminescence and nonlinear optical properties).1 Lower melting organic halometallates have been investigated as soft materials (ionic liquid crystals or ionic liquids).2 Both solids and liquids have been studied quite extensively by solid-state and ionic liquid chemists, but each group adopts their own research methodology and approaches. In the solid state, the focus is on crystal structure and material properties. Chlorometallate ionic liquids, on the other hand, have been used for electrochemistry,4 catalysis5 and separations,6 their anionic speciation has been thoroughly investigated,7–10 but they have rarely been used for inorganic syntheses,11 and never for the systematic study on the ionothermal preparation of organic/inorganic hybrid materials (i.e. direct crystallisation from the molten ionic liquid). It would be interesting to adopt a more holistic approach: to prepare a set of halometallates based on the same metal halide, and (through changes of the cation and the reactant ratios) access both groups of materials: ionic liquids and crystalline organic/inorganic hybrid materials. In this study, chloroplumbate(n) salts were chosen as a model system, due to their flexibility in structural arrangements, with varying coordination numbers and stereochemistry.12,13

Solid state perspective

The structural organisation of homoleptic chloroplumbate(n) anions with organic cations is governed by: (a) the very flexible coordination sphere of lead(II), influenced by the ‘inert electron pair’ and relativistic effects,14 (b) the flexible coordination environments of halide anions, and (c) steric and hydrogen bonding effects deriving from the cation. This has given rise to a plethora of chloroplumbate(n) structures, from rare discrete anions,15,16 to much more common 1D strands13,17 and 2D sheets of polyanions, often forming perovskite-type materials.13

In order to tune the electro-optic properties of these materials, attempts have been made to modify the solid-state structures of chloroplumbate(n) materials in a controlled
manner. This can be achieved by using deliberately selected cations, able to form strong hydrogen bonds or to induce specific steric effects. For example, amine-functionalised cations (e.g., 2-methylpentane-1,5-diammonium or N,N'-dimethylpyperazinium) were demonstrated to direct the crystal packing by hydrogen bonding, while the combination of hydrogen bonding and steric effects deriving from cations has been shown to induce the formation of discrete chloroplumbate(II) anions, and extraordinary arrangements of the chloroplumbate(II) units, such as channel polymers. Besides the influence of cation, the choice of halide (Cl, Br, or I) was reported to have some effect on the structural arrangement. Noteworthy, the molar ratio of the reactants (expressed as mole fraction of lead(II) halide, \(X_{\text{PbCl}_2}\)) was not considered as a key variable in the syntheses.

Chloroplumbate(II) organic/inorganic hybrid salts are typically prepared by crystallisation from acidic aqueous solutions. Ionothermal syntheses from ionic liquids have been limited to two publications, reporting jointly five systems based on 1-alkyl-3-methylimidazolium bromoplumbates, but none based on chloroplumbates. From this perspective, it appeared interesting to make the first attempt to prepare chloroplumbate(II) organic/inorganic hybrid materials via the ionothermal route. Furthermore, it seemed worthwhile to analyse the influence of \(X_{\text{PbCl}_2}\) of the melt on the structure of the crystalline products.

### Ionic liquid perspective

Ionic liquids based on halometallate species can be characterised (in their liquid phase) by dynamic equilibria between several anionic species. The presence and concentration of each species is known to depend on the metal, and on the mole fraction of metal halide, \(X_{\text{MX}}\), whereas the liquid-state anionic speciation (i.e., for example abundant water on chloroaluminates) systems based on various cations. Consequentially, the variables taken into account when studying halometallate ionic liquids differ from those investigated routinely by solid-state chemists. Importantly, in the liquid state, only discrete halometallate anions (monomers, dimers, or sometimes trimers and tetramers) may be present; the formation of polyanionic structures naturally results in the crystallisation of a solid.

There have been no room-temperature chloroplumbate(II) ionic liquids reported to date. This study presents an exciting opportunity to prepare and investigate a new group of metal-based ionic liquids.

### Approach and methodology in this work

In this paper, a range of chloroplumbate(II) organic salts, based on two cations: trihexyl(tetradecyl)phosphonium, \([\text{P}_{6.6.6.14}^+\] and 1-ethyl-3-methylimidazolium, \([\text{C}_{2}\text{mim}]^+\), was prepared via the ionothermal route. The variables taken into account were: the mole fraction, \(X_{\text{PbCl}_2}\), and the organic cation structure. Depending on their melting point, the products were studied as ionic liquids, as crystalline materials and, where possible, in both states. The relationship between the speciation of chloroplatinate(II) anions in the liquid state, and the structure of crystalline materials synthesised via the ionothermal route, was studied.

### Experimental

Lead(II) chloride, (CR BDH Chemicals Ltd., 99%), was dried under high vacuum (120 °C, 3 d, 10⁻² mbar) and stored in a dinitrogen-filled glovebox (MBraun LabMaster dp; <0.1 ppm O₂ and H₂O). Trihexyl(tetradecyl)phosphonium chloride (97.7% by ³¹P NMR spectroscopy) was provided by Cytec Industries, Inc., benzyl(triphenyl)phosphonium chloride was purchased from Sigma-Aldrich. 1-Ethyl-3-methylimidazolium chloride was prepared as described elsewhere, dried under high vacuum (75 °C, 7 d, 10⁻² mbar) and stored in the glovebox.

### Synthesis of chloroplumbate(II) systems

Chloroplumbate(II) systems based on \([\text{P}_{6.6.6.14}^+\] and \([\text{C}_{2}\text{mim}]^+\) were prepared for a wide range of compositions (0.05 ≤ \(X_{\text{PbCl}_2}\) ≤ 0.75).

Syntheses were carried out in the glovebox. Typically, an appropriate amount of [cation]Cl was weighed into a sample vial (10 cm³) containing a PTFE-coated stirring bar. An appropriate amount of lead(II) chloride was then carefully added to achieve the desired ratio of the reactants. Subsequently, the sample vial was closed with a cap, placed in a multi-well heater-stirrer, and stirred vigorously (80–150 °C, overnight). The samples were stored in the glovebox prior to study. Accurate masses of reactants are given in Table 1.

### Analytical methods

**Raman spectroscopy.** Raman spectra were recorded using a PerkinElmer Raman Station 400F spectrometer, with a 785 nm focused laser beam. The neat samples were loaded in the

glovebox to quartz cuvettes, which were subsequently sealed with parafilm and removed from the glovebox immediately prior to the measurement. Unless otherwise stated, forty 2-second scans were recorded for each composition.

[\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e}]\text{Cl–PbCl}_2 was stirred overnight with a small amount of activated charcoal (80 °C, overnight) to remove fluorescent impurities. The charcoal was allowed to partially settle (but was not removed) prior to the Raman measurements; its presence did not interfere with the measurements.

This system and a solid [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 system were measured at ambient temperature. To obtain Raman spectra of molten samples of the [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 system, the samples (sealed in quartz cuvettes) were heated with a heat gun above the melting point (150 °C), and two 4-second scans were immediately recorded. The temperature drop measured within this time (for a sample outside of spectrometer) was 4 °C, hence the temperature of the experiment is assumed to be 148 ± 2 °C. For comparison, several samples of the [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{s}]\text{Cl–PbCl}_2 system were also tested under these conditions.

**NMR spectroscopy.** In the glovebox, neat ionic liquids were heated to decrease viscosity and loaded into NMR tubes (5 mm, borosilicate glass) containing sealed capillaries with d_6-dimethylsulfoxide (an external lock). The tubes were closed with a standard cap, sealed with parafilm, and removed from the glovebox immediately prior to measurement.

All spectra were measured at 80 °C, using a Bruker DRX 500 spectrometer. The $^{207}\text{Pb}$ NMR spectra of the [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{s}]\text{Cl–PbCl}_2 system were recorded at 104.8 MHz. Lead(ii) nitrate in D_2O (1.0 M solution) was used as an external reference ($\delta = -1963$ ppm). $^{207}\text{Pb}$ is a spin 1/2 nucleus, characterised by medium sensitivity ($2.00 \times 10^{-3}$ relative to $^1\text{H}$ natural abundance).

**Viscosity.** Viscosity measurements were carried out using a Bohlin Gemini cone-and-plate viscometer and rheometer with a Bohlin Instruments Peltier temperature control and a stainless steel 4/40 spindle. The measurements were taken at temperatures between 20 to 100 °C, in 5 °C increments. Tested samples were loaded in syringes in the glovebox, transferred immediately to the apparatus. The measurements were carried out under a stream of dry nitrogen gas.

**Differential scanning calorimetry (DSC).** All scans were obtained using a TA DSC Q2000 model with a TA Refrigerated Cooling System 90 (RCS) and an autosampler. The samples were sealed in the glovebox in TA Tzero alodined lids. The DSC chamber was filled with dry dinitrogen.

For [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{s}]\text{Cl–PbCl}_2, the temperature was ramped four times between $-90$ and 80 °C, at 5 °C min$^{-1}$, each time stabilised for 5 min at minimum and maximum temperature. All scans for the liquid samples were modulated. For [\text{C}_2\text{mim}]\text{Cl–PbCl}_2, the temperature was ramped three times between $-90$ to 200 °C, at 5 °C min$^{-1}$, each time stabilised for 5 min at minimum and maximum temperature.

**Crystallography.** Single crystals were grown directly from the melt. Samples of [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 salts were cooled in air-tight vials and removed from the glovebox. They were placed in a heating block with a computer-controlled heating/cooling regime, heated to 150 °C and cooled at 1 °C h$^{-1}$ to ambient temperature.

Crystal data for [\text{C}_2\text{mim}]\text{[PbCl}_3\text{]} were collected using a Bruker Nonius KappaCCD diffractometer with a FR591 rotating anode and a molybdenum target at ca. 120 K in a dinitrogen stream. Lorentz and polarisation corrections were applied. The structure was solved by direct methods. Hydrogen-atom positions were located from difference Fourier maps and a riding model with fixed thermal parameters ($U_{eq} = 1.2U_{eq}$ for the atom to which they are bonded; 1.5 for methyl), was used for subsequent refinements. The function minimised was $\Sigma [w(F_{o}^{2} - |F_{c}|^{2})]$ with reflection weights $w = 1/[\sigma^2(F_{o}^{2})^2] + (g_1P)^2 + (g_2P)]$, where $P = [\max(|F_{o}|^2 + 2|F_{c}|^2)/3$. The SHELXTL package and OLEX2 were used for structure solution and refinement.

**Results and discussion**

**Synthesis**

The [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 system was chosen to study because the [\text{C}_2\text{mim}]$^+$ cation is a popular motif in design of ionic liquids and, at the same time, the [\text{C}_2\text{mim}]\text{Br–PbBr}_2 system is known to give organic/inorganic hybrid materials which exhibit nonlinear optical behaviour. Although analogous materials based on the [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 system are not known, this system was expected to yield materials of similar properties.

The [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e}]\text{Cl–PbCl}_2 system, incorporating a bulky cation with long, flexible alkyl chains, was designed to give room-temperature ionic liquids, facilitating liquid-state speciation studies.

A range of compositions of both systems was prepared. In the course of isothermal synthesis (i.e. at 80–150 °C) homogeneous melts were obtained for $\chi_{\text{PbCl}_3} \leq 0.45$. For $\chi_{\text{PbCl}_3} > 0.45$, samples contained a white powder, identified as unreacted lead(ii) chloride by Raman spectroscopy.

At ambient temperature, all samples of [\text{C}_2\text{mim}]\text{Cl–PbCl}_2 were crystalline solids, whilst all compositions of [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e}]\text{Cl–PbCl}_2 were viscous liquids (see Fig. 1), apart from the lead(ii) chloride suspended in $\text{PbCl}_2$ system, the $\text{C}_2\text{mim}$ system was expected to yield materials of similar properties.

![Fig. 1](image-url) Photographs of the room temperature ionic liquids of the selected samples of the [\text{P}_6\text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{e} \text{s}]\text{Cl–PbCl}_2 system; (a) $\chi_{\text{PbCl}_3} = 0.28$ and (b) $\chi_{\text{PbCl}_3} = 0.37$. 

\[ \text{equation} \]
temperature ionic liquids based on chloroplumbate(II) anions reported to date.

[C₂mim][Cl]–PbCl₂ system

Solid state speciation. All compositions of the [C₂mim][Cl]–PbCl₂ system had well-defined melting points; more than one melting point was found for several samples.† Based on DSC measurements, a phase diagram has been constructed (Fig. 2); four crystalline phases (A–D) were detected. Phase A (found for \(X_{PbCl2} \leq 0.30\)) can be assigned to [C₂mim][Cl] and phase D (detected for \(X_{PbCl2} \geq 0.45\)) to lead(II) chloride. The remaining phases, B and C, are presumably two different chloroplumbate(II) compounds.

Analysing the phase diagram alone, the crystal structures of phases B and C are expected to be polymeric, rather than contain discrete anions. This is supported by relatively high melting points, as well as by incongruent melting of both phases. Based on the stoichiometry, general formulas of \([\text{C}_2\text{mim}]_2\text{PbCl}_4\) and \([\text{C}_2\text{mim}]\text{PbCl}_3\) could be tentatively suggested for phases B and C, respectively.

As described in the introduction, chloroplumbate(II) structures based on organic cations feature a plethora of various structural arrangements. The known compounds are characterised by various \(X_{PbCl2}\) values, and their structure depends strongly on the cation. Unfortunately, in the literature, there are no chloroplumbate(II) structures based on the imidazolium cation. Six bromoplumbate(II) crystalline materials based on imidazolium cations, five synthesised ionothermally, and one grown from an aqueous solution, are listed in Table 2.

Four of them were isostructural, containing 1D chains of pentacoordinate \(\text{PbBr}_5\) units in the form of bridging basal chlorine atoms from tetragonal pyramids, effectively giving \([\text{C}_2\text{mim}]\text{PbBr}_3\) stoichiometric compounds (\(X_{\text{PbBr2}} = 0.50\)), as shown in Fig. 3a. Another structure of \([\text{C}_2\text{mim}]\text{PbBr}_3\) formula and \(X_{\text{PbBr2}} = 0.50\) stoichiometry formed 1D strands of face-sharing octahedra (PbBr₆), as shown in Fig. 3b. Finally, a structure of a different stoichiometry (\(X_{\text{PbBr2}} = 0.33\)), featuring a trinuclear \(\text{Pb}_3\text{Br}_{12}\) anion depicted in Fig. 3c, was determined for \([\text{C}_4\text{mim}]\text{PbBr}_3\). In all structures, there was a dense network of hydrogen bonds between the bromoplumbate(II) strands and the surrounding cations.

In analogy, it may be expected that phases B and C in the [C₂mim][Cl]–PbCl₂ system (Fig. 2) contain polymeric 1D strands: \([\text{C}_2\text{mim}]_2\text{PbCl}_4\) and \([\text{C}_2\text{mim}]\text{PbCl}_3\), respectively.

To determine the precise structure of the anion, a single crystal was grown directly from the molten \(X_{\text{PbCl2}} = 0.40\) composition. Its structure contained infinite chloroplumbate(II) strands formed by edge-sharing tetragonal pyramids of pentacoordinate \(\text{PbCl}_5\) units (Fig. 4), with an overall stoichiometry of \([\text{C}_2\text{mim}]\text{PbCl}_3\), \(X_{\text{PbCl2}} = 0.50\). This confirms that phase C (Fig. 2) is isostructural with the analogous bromoplumbate(II) salt, shown in Table 2 and Fig. 3a. In particular, the mean \(\text{Cl}_{\text{ap}}-\text{Pb}-\text{Cl}_{\text{eq}}\) at 88(6)° is the same as that of the analogous \(\text{Br}_{\text{ap}}-\text{Pb}-\text{Br}_{\text{eq}}\) at 89(5)°, and both structures show strong evidence for the existence of a stereochemically active lone pair.

Fig. 3  Connectivity in bromoplumbate(II) oligomeric or polymeric chains found in bromoplumbate(II) organic/inorganic hybrid materials based on the [C₂mim]⁺ cation,21,22,28
not interacting with any of the cationic hydrogen-bond donor sites.

The asymmetric unit contains one Pb atom, three different Cl\(^{-}\) anions and one imidazolium cation. The Pb atoms form three shorter bonds to chloride anions ranging from 2.629(1) to 2.778(1) Å, and have two longer contacts at 3.074(1) and 3.108(1) Å (Fig. 5). Four of the five chloride anions are \(\mu_2\)-bridging to the neighbouring Pb atoms and link the five-coordinate, edge-sharing, distorted tetragonal pyramids into strands along the \(a\)-axis. The sixth position of the ‘octahedron’ is vacant in the crystal structure, and is presumably occupied by a lone pair of electrons from the lead(II).

Two of the three ring protons of the \([C_2\text{mim}]^+\) cations are involved in C–H⋯Cl hydrogen bonding (see Fig. 6), with the C2–H and C3–H protons showing relatively weak interactions at 2.906(1) and 2.985(1) Å, respectively. Shorter C–H⋯Cl contacts to the \(\{\text{PbCl}_3\}^n\) strands are found for the N-methyl and terminal CH3 group of the N-ethyl group, ranging from 2.697(7) to 2.885(7) Å, respectively.

Each imidazolium cation is hydrogen bonded (via both the ring protons and two N-methyl protons) to the adjacent \(\{\text{PbCl}_3\}^n\) strands, resulting in a three-dimensional C–H⋯Cl network, shown in Fig. 7. The crystallographic data are summarised in Table 3.

To confirm the identification of phase B, a single crystal was grown (directly from the melt) from \(x_{\text{PbCl}_2} = 0.33\). Unfortunately, the crystalline material was extremely hygroscopic and decomposed prior to measurement. Therefore, to gain a better insight into the possible structure of phase B, Raman spectra were recorded for a range of \([C_2\text{mim}]\text{Cl}–\text{PbCl}_2\) compositions.

In \([C_2\text{mim}]_{2}\text{PbCl}_4\) (higher \(x_{\text{PbCl}_2}\) values, phase C), lead(II) is pentacoordinate, with shorter Pb–Cl bonds and therefore blueshifted vibrational frequencies are to be expected. In \([C_2\text{mim}]_{3}\text{PbCl}_5\) (lower \(x_{\text{PbCl}_2}\) values), lead is anticipated to be hexacoordinate, with longer Pb–Cl bonds, and therefore the vibrational frequencies are expected to be red-shifted.\(^{36}\)

Bands characteristic of the Pb–Cl\(_t\) (terminal) stretching frequencies fall between ca. 200 and 300 cm\(^{-1}\).\(^{34}\) The ratio of a bridging metal–halogen stretching frequency to a terminal
metal–halogen stretching frequency, $\zeta$, is typically between 0.60 and 0.85. The relevant Raman bands recorded for the [C$_2$ mim]Cl–PbCl$_2$ system are detailed in Fig. 8 and Table 4.

For higher $\chi_{\text{PbCl$_2$}}$ (phase C), a band for Pb–Cl$_{\text{t}}$ is found around 226 cm$^{-1}$, and a band for Pb–Cl$_{\text{b}}$ (bridging) around 173 cm$^{-1}$, with $\zeta$ = 0.75. For lower $\chi_{\text{PbCl$_2$}}$ values (phase B), both Pb–Cl stretching frequencies are red-shifted to around 218 cm$^{-1}$ and 163 cm$^{-1}$, respectively, with $\zeta$ = 0.77. Significantly, Raman spectroscopy is less sensitive than DSC for the detection of small amounts of new phases, and hence they are detected at lower $\chi_{\text{PbCl$_2$}}$ values in Fig. 2 than in Fig. 8.

Phase C, present for $\chi_{\text{PbCl$_2$}} > 0.33$, was unambiguously identified as [C$_2$ mim]{PbCl$_3$}, with pentacoordinate lead(II) strands (Fig. 3–7). Raman spectra for phase B, present predominantly for $\chi_{\text{PbCl$_2$}} < 0.33$, strongly suggest that lead(II) is hexacoordinate (viz. red-shifted bands, indicating longer Pb–Cl bonds). The proposed structure of [C$_2$ mim]{PbCl$_4$} contains most likely one of the two structural motifs: 2D sheets (Fig. 9a) or 1D strands (Fig. 9b). Perovskite-like, 2D chloroplumbate(II) layers shown in Fig. 9a are the dominant structural arrangements in chloroplumbate(II) organic/inorganic hybrid materials with $\chi_{\text{PbCl$_2$}} = 0.33$ stoichiometry. Alternatively, the presence of strongly hydrogen-bonding [C$_2$ mim]$^+$ cation
may direct the formation of infinite 1D chloroplumbate(n) chains with edge-sharing octahedra (Fig. 9b), in analogy to bromoplumbate cations; however, such arrangements are very rare in chloroplumbate(u) systems.31

**Liquid state speciation.** Although the solid-state speciation for the [C₄mim]Cl–PbCl₂ system as a function of composition has been resolved, no direct information about the speciation of the melt has been provided as yet. Incongruently melting has been resolved, no direct information about the speciation of molten chloroplumbate(II) inorganic salts; the distribution of the anions as a function of composition was not resolved. To investigate this, different techniques, such as multinuclear NMR spectroscopy, should be used. Therefore, room temperature ionic liquid system based on the [P₆₆₆₁₄]⁺ cation was prepared.

The [P₆₆₆₁₄]⁺ cation was selected to frustrate crystallisation; DSC measurements revealed remarkably low first-order phase transitions (−65 to −70 °C; 1 to 6 kJ mol⁻¹) for all compositions.† The partial phase diagram is shown in Fig. 11. A single first-order found for the lower XₚbCl₂ values were tentatively assumed to correspond to the formation of [P₆₆₆₁₄][PbCl₄], lowering the melting point of [P₆₆₆₁₄]Cl.

**Fig. 10** Raman spectra (148 ± 2 °C, liquid state) of the [C₄mim]Cl–PbCl₂ system. The bands indicated in red originate from [PbCl₄]²⁻ and those indicated in blue from [PbCl₃]⁻.

![Fig. 11](image2.png)

**Fig. 11** Phase diagram of the [P₆₆₆₁₄]Cl–PbCl₂ system.
For $\chi_{\text{PbCl}_2} \geq 0.40$, a second peak was found at higher temperatures, possibly corresponding to $[\text{PbCl}_6]^{2-}$. The relatively high phase transition for an ionic liquid based on the singly charged $[\text{PbCl}_4]^{2-}$ might be attributable to the presence of a trigonal planar ($D_{3h}$), rather than a pseudo-tetrahedral ($C_4v$) anion.

$^{207}$Pb NMR spectroscopy (which has a normal chemical shift range from $-5500$ to $6000$ ppm) was used to study trends in the liquid state speciation as a function of composition. Spectra acquired for $[\text{PbCl}_6]^{2-}\text{PbCl}_2$ (at 80 °C to lower the viscosity) are shown in Fig. 12. Single peaks were found for each composition, indicating the existence of exchange between the chloroplumbate(n) species, rapid on the NMR time scale. The $^{207}$Pb NMR signal is shifted within the range 960 to 1360 ppm; peak width also changes noticeably.

To facilitate quantitative analysis of the spectroscopic data, the chemical shift, $\delta$, and the peak width at half-height, $\Delta \nu_{1/2}$, were plotted as a function of composition, $\chi_{\text{PbCl}_2}$ (Fig. 13).

The $\Delta \nu_{1/2}$ values depend on the electronic density on the $^{207}$Pb nuclei, which in this study is related directly to the coordination number of chloroplumbate(n) complexes. The peak width, $\Delta \nu_{1/2}$, is influenced by the electronic environment of the nuclei and by the viscosity of the medium. The electronic environment is related to the geometry of the anion, which depends on coordination number and on the stereochemical activity of the lone pair. To identify the contribution of the electronic environment, the viscosity of the samples at 80 °C was plotted as a function of temperature (Fig. 13).

The $\delta$ values increase from the starting plateau between $\chi_{\text{PbCl}_2} = 0.05$ and 0.15 to another plateau between $\chi_{\text{PbCl}_2} = 0.45$ and 0.55 (see Fig. 13, upper, with three ‘speciation zones’: A, B and C). This indicates the existence of two chloroplumbate(n) species in equilibrium with each other, one predominant for low $\chi_{\text{PbCl}_2}$ (A), the other predominant for high $\chi_{\text{PbCl}_2}$ (C), and both present in significant concentrations for the intermediate compositions (B), where they must be in dynamic equilibrium. The $\chi_{\text{PbCl}_2} < 0.30$ compositions (A) contain high concentrations of chloride; as expected, the $^{207}$Pb NMR signal is shifted upfield, indicating higher electron density on the metal nuclei (i.e. relatively high coordination number). In contrast, the $\chi_{\text{PbCl}_2} > 0.45$ compositions (C) contain lower chloride concentrations, leading to lower coordination number of lead(n), and hence a downfield shift in the $^{207}$Pb NMR signal.

Considering the viscosity of neat ionic liquids, signals for $\chi_{\text{PbCl}_2} < 0.30$ (A) are relatively narrow (<100 Hz), as shown in Fig. 12. This indicates high symmetry species, such as octahedral $[\text{PbCl}_6]^{2-}$ or tetrahedral $[\text{PbCl}_4]^{2-}$. The increase in the $\Delta \nu_{1/2}$ values for these compositions is paralleled by the increase in viscosity, as expected when replacing the small negative chloride ion with the larger, doubly or quadruply charged chloroplumbate(n) anions (cf. ref. 9 and 10).

The peak width for $\chi_{\text{PbCl}_2} = 0.30$ is much greater than that for lower $\chi_{\text{PbCl}_2}$ values (A). Furthermore, for $\chi_{\text{PbCl}_2}$ lying between 0.30 and 0.45 (B), the $\Delta \nu_{1/2}$ values increase as the viscosity of the samples decrease. This is indicative of the presence of a new species, characterised by lower charge inducing the viscosity decrease. The signal broadening derives from the...
dynamic exchange between two chloroplumbate(n) anions (vide supra), and also may contain a contribution from the lower symmetry species.

Signals corresponding to $\chi_{PbCl_{3}} > 0.45$ (C) are broad, with the $\Delta_{4/3}$ values reaching a plateau for the $\chi_{PbCl_{3}} > 0.50$ compositions. A plateau reached by both $\delta$ and $\Delta_{4/3}$ may suggest the existence of one predominant chloroplumbate(n) anion of low symmetry, but more likely it points towards an equilibrium state involving two chloroplumbate(n) anions, $[\text{PbCl}_{4}]^{2-}$ and $[\text{PbCl}_{3}]^{-}$; since PbCl$_{2}$ precipitates for all $\chi_{PbCl_{3}} > 0.45$ compositions, the composition containing exclusively $[\text{PbCl}_{3}]^{-}$ anions is never formed.

There is a paucity of $^{207}$Pb NMR data for chloroplumbate(n) ionic liquids. Based on the evidence presented here, the most plausible suggestion for the identity of chloroplumbate(n) species would be: $[\text{PbCl}_{4}]^{2-}$ in A, predominance of $[\text{PbCl}_{3}]^{-}$ equilibrated with $[\text{PbCl}_{4}]^{2-}$ in C, and a dynamic exchange between the two anions in B. The $[\text{PbCl}_{3}]^{-}$ anion is of the lowest symmetry, $D_{3h}$, and its single charge would result in a viscosity decrease. $[\text{PbCl}_{4}]^{2-}$ would produce more viscous ionic liquids, with signals corresponding to higher symmetry.

To confirm this speciation, Raman spectra of the $[P_{6} 6 6 14]Cl$–PbCl$_{2}$ system were recorded at ambient temperature. Spectra of freshly prepared compositions were of very poor quality due to fluorescence, deriving from impurities which originate from the organic chloride precursor, $[P_{6} 6 6 14]Cl$. In most cases, this could be solved by recrystallisation of [cation]-Cl prior to the synthesis of chloroplumbate(n) systems, but this is not practical in the case of $[P_{6} 6 6 14]Cl$, which is a commercial room temperature ionic liquid (Cyphos 101). To tackle this problem, the prepared compositions were stirred overnight with activated charcoal. The presence of small amounts of suspended charcoal did not interfere with the measurements; acquired spectra were of acceptable quality and were used in this work.

The regions of Raman spectra characteristic of Pb–Cl vibrations are shown in Fig. 14. Two chloroplumbate(n) anions were detected, one present in all compositions (band at ca. 245 cm$^{-1}$), and another found for $\chi_{PbCl_{3}} \geq 0.33$ (band at ca. 267 cm$^{-1}$). The vibrational frequencies are higher than typical for Pb–Cl bonds; this indicates low coordination numbers and very short bonds, supporting the presence of $[\text{PbCl}_{4}]^{2-}$ in all compositions and $[\text{PbCl}_{3}]^{-}$ for $\chi_{PbCl_{3}} \geq 0.33$.

In order to assess the temperature effect, several spectra for the $[P_{6} 6 6 14]Cl$–PbCl$_{2}$ system were recorded also at 148 ± 2 °C, but the changes in the stretching frequencies were negligible (within 2 cm$^{-1}$).

It is noteworthy that PbCl$_{2}$ precipitates for compositions where $\chi_{PbCl_{3}} > 0.45$, although $[P_{6} 6 6 14]Cl$–PbCl$_{3}$ might be expected to form stoichiometrically at $\chi_{PbCl_{3}} \approx 0.50$. This suggests that the equilibrium concentrations of both chloroplumbate(n) anions (see the equilibria shown in eqn (1)) are shifted quite strongly to the left by the precipitation of lead(III) chloride.

$$[\text{PbCl}_{4}]^{-}\rightleftharpoons [\text{PbCl}_{3}]^{-} + \text{Cl}^{-}$$

Comparison of two ionic liquid systems

It is striking, that the Pb–Cl stretching frequencies for $[\text{PbCl}_{4}]^{2-}$ and $[\text{PbCl}_{3}]^{-}$ in the liquid $[P_{6} 6 6 14]Cl$–PbCl$_{2}$ system (245 and 267 cm$^{-1}$, respectively) are strongly blue-shifted compared to the same vibrations in molten $[C_{2}\text{mim}]Cl$–PbCl$_{2}$ (224 and 237 cm$^{-1}$). This shows that the structures of chloroplumbate(n) anions are very flexible, as is commonly found for complexes containing a stereochemically active lone pair. For example, the stretching frequency for $[\text{PbCl}_{3}]^{-}$ was found to be 237 cm$^{-1}$ in molten $[C_{2}\text{mim}]Cl$–PbCl$_{2}$, 249 cm$^{-1}$ in aqueous solution$^{17}$ and 267 cm$^{-1}$ in $[P_{6} 6 6 14]Cl$–PbCl$_{2}$ (liquid). As already pointed out by Dracopoulos et al.$^{34}$ the trigonal planar structure of $[\text{PbCl}_{3}]^{-}$ is expected to have shorter Pb–Cl bonds than the pseudo-tetrahedral one. Consequently, in the hydrophobic environment of $[P_{6} 6 6 14]Cl$–PbCl$_{2}$, the structure of $[\text{PbCl}_{3}]^{-}$ appears to be very close to planar, with short lead–chlorine bonds. In an aqueous solution, the anion distorts towards $C_{3v}$ symmetry. Finally, in hydrophilic $[C_{2}\text{mim}]Cl$–PbCl$_{2}$, with well-documented tendency of the cation to form strong hydrogen bonds with halometallate anions,$^{10}$ a pseudo-tetrahedral structure of the $[\text{PbCl}_{3}]^{-}$ anion is expected, with well-pronounced influence of the free electron pair (for comparison, viz. the analogous crystal structure of $[C_{2}\text{mim}]\text{SnCl}_{3}$,$^{10}$ with a dense network of hydrogen bonds and pseudo-tetrahedral anion). However, in contrast to the tin(n) system, the lead(n) anion forms infinite 1D chains upon crystallisation.
Conclusions

The first examples of chloroplumbate(II) room temperature ionic liquids are reported. Furthermore, the first organic/inorganic chloroplumbate(II) materials prepared via the ionothermal route are described.

At ambient temperature, the imidazolium system is in the solid state, whereas the phosphonium system is in the liquid state, giving the interesting opportunity to compare and contrast these systems. Based on the phase diagrams and Raman spectra for both systems, on $^{207}$Pb NMR spectroscopy of the $[\text{PbCl}_3]$ anions depends strongly on the cation. As shown by Raman spectroscopy for both systems, on 207Pb NMR spectroscopy of the chloro-plumbate(II) polymeric strands is derived directly from the liquid-state structure of chloroplumbate(II) monomeric anions.

In the liquid phase, the geometry of chloroplumbate(II) anions depends strongly on the cation. As shown by Raman spectroscopy, in the hydrophobic environment of tetraalkylphosphonium cations, $[\text{PbCl}_3]$ is close to trigonal planar, with extremely short Pb–Cl bonds, whilst in the presence of strongly hydrogen-bonding $[\text{C}_2\text{mim}]^-$ cations, pseudo-tetrahedral geometry, with well-pronounced influence of the free electron pair, is favoured.
