Final State Interactions in the Near-Threshold Production of Kaons from Proton-Proton Collisions*

Abstract
We analyse the \(pp \rightarrow p\Lambda K\) cross section recently measured at COSY arguing that the enhancement of the production cross section at energies close to the reaction threshold should be due to the \(\Lambda p\) final state interaction. We find that the experimental \(\Lambda p\) elastic scattering data as well as the predictions from the Jülich-Bonn model are in reasonable agreement with the new results on \(K^+\)-meson production. We propose to study directly the final state interaction by measurements of the cross section as a function of the hyperon momentum in the \(\Lambda p\) cm system.

Recently, the COSY-11 \cite{1} and COSY-TOF Collaborations \cite{2} measured the 
\(pp \rightarrow p\Lambda K^+\) cross section at energies close to the reaction threshold. The experimental 
\(K^+\) yield found is twice as large as predicted in Ref. \cite{3} and by Fäldt and Wilkin \cite{4} for excess energies \(\epsilon < 7\) MeV whereas both models reproduce the data 
for \(\epsilon > 50\) MeV. Here we will argue that this enhancement is due to \(\Lambda p\) Final State 
Interactions (FSI).

In Ref. \cite{3} the total cross section for the 
\(pp \rightarrow p\Lambda K^+\) reaction has been calculated 
within the One-Boson-Exchange (OBE) model including both the pion and kaon 
exchanges in line with the analysis performed at high energies \cite{5}. In the latter 
work the FSI between the \(\Lambda\)-hyperon and the proton has been neglected for reasons 
of simplicity but also due to the large uncertainty in the low energy \(\Lambda p\) scattering 
cross section \cite{6, 7}. The free parameters of the model, i.e. the coupling constants 
and the cut-off parameters of the form factors for the \(NN\pi\) and \(NYK\) vertices, were 
fit to the experimental data taken at high energies \cite{9}.

On the other hand, Fäldt and Wilkin \cite{4} calculated the energy dependence of 
the \(pp \rightarrow p\Lambda K^+\) cross section by using only the one pion exchange in line with the 
calculations from Ref. \cite{8}. Moreover, it was assumed that the production amplitude 
is constant and is related to the \(pp \rightarrow pp\eta\) reaction. The FSI between the \(\Lambda\)-hyperon 
and the proton then was incorporated via the effective range approximation. With 
only a single free parameter fixed by the \(\eta\) production data, the calculations from 
Ref. \cite{4} reasonably reproduced the \(pp \rightarrow p\Lambda K^+\) cross section at \(\epsilon = 2\) MeV \cite{10} available at that time. Note, however, that the FSI correction factor at this energy 
is about \(\simeq 14\) and therefore the production amplitude due to the pion exchange itself 
is very small. On the other hand, Tsushima et al. \cite{11} calculated the 
\(pp \rightarrow p\Lambda K^+\) production amplitude in a microscopic model which illustrates that near threshold 
the pion exchange contribution to the reaction is small and underestimates the most 
recent data from COSY \cite{1, 2} by about a factor \(\simeq 10\). Our present work is to clarify 
these partly conflicting results.

We recall that the total cross section for the reaction 
\(pp \rightarrow p\Lambda K^+\) is obtained by integrating the differential cross section 
\(d^2\sigma/dtds_1\) over the available phase space,

\[
\sigma = \int dtds_1 \frac{d^2\sigma}{dtds_1} = \frac{1}{2^9\pi^3q^2s} \int dtds_1 \frac{qK}{\sqrt{s_1}} |M(t, s_1)|^2.
\]

Here \(s\) is the squared invariant mass of the colliding protons, \(q\) is the proton momentum 
in the center-of-mass while \(t\) is the squared 4-momentum transfered from the 
initial proton to the final hyperon or proton in case of the kaon or pion exchange, 
respectively. Moreover, \(s_1\) is the squared invariant mass of the \(Kp\) or \(KA\) system, 
respectively, while \(qK\) is the kaon momentum in the corresponding center-of-mass 
system. In Eq. \cite{10} \(|M|\) is the amplitude of the reaction which is an analytical 
function of \(t\) and \(s_1\).

Let us start with the experimental \(pp \rightarrow p\Lambda K^+\) cross section and extract the 
reaction amplitude averaged over \(t\) and \(s_1\) by taking \(|M|^2\) out of the integral in 
Eq. \cite{10}. The average reaction amplitude then can be determined by comparing \(\sigma\) 
from Eq. \cite{10} with the corresponding experimental cross section from Refs. \cite{1, 2, 3}. 
The results for the average matrix element \(|M|\) are shown in Fig. \ref{fig:1} as function of
the excess energy ε = \sqrt{s} - m_p - m_\Lambda - m_K, with m_p, m_\Lambda and m_K being the mass of the proton, Λ-hyperon and kaon, respectively. Obviously, the matrix element |M| as evaluated from the data is not constant and decreases substantially with the excess energy ε.

Following the Watson-Migdal approximation the total reaction amplitude can be factorized in terms of the production |M_{prod}| and FSI amplitude |A_{FSI}|. Since at high energies the FSI is negligible, the latter amplitude should converge to 1 for ε → ∞. Within the OBE model the squared production amplitude, for instance for the pion exchange, is given as \[3, 5, 8\]

\[ |M_{prod}(t, s_1)|^2 = g_{NN\pi}^2 \frac{t}{(t - \mu^2)^2} \left[ \frac{\Lambda_\pi^2 - \mu^2}{\Lambda_\pi^2 - t} \right]^2 |A_{\pi^0 p \to \Lambda K^+}(s_1)|^2, \tag{2} \]

where \(g_{NN\pi}\) is the coupling constant and \(\mu\) is the pion mass. The form factor of the \(NN\pi\) vertex is given in brackets with \(\Lambda_\pi\) denoting the cut-off parameter. In Eq. (2) \(|A|\) is the amplitude for the reaction \(\pi^0 p \to \Lambda K^+\), which can be calculated microscopically within the resonance model or evaluated from the experimental data as

\[ |A_{\pi^0 p \to \Lambda K^+}(s_1)|^2 = 16\pi s_1 \frac{q_\pi}{q_K} \sigma_{\pi^0 p \to \Lambda K^+}(s_1), \tag{3} \]

where \(q_\pi\) is the pion momentum in the \(\Lambda K^+\) center-of-mass system and \(\sigma_{\pi^0 p \to \Lambda K^+}\) is the physical cross section.

Since \(m_\Lambda + m_K \leq \sqrt{s_1} \leq m_\Lambda + m_K + \epsilon\), thus close to the \(pp \to p\Lambda K^+\) reaction threshold the amplitude \(|A_{\pi^0 p \to \Lambda K^+}|\) is almost constant. Moreover, the 4-momentum transfer squared \(t\) is a slowly varying function of energy at low \(\epsilon\) as shown in Fig. 2a). Therefore it is a quite reasonable approximation to assume that the production amplitude \(|M_{prod}|\) is almost constant near the threshold. Similar arguments can be set up for the kaon exchange amplitude. We thus conclude that the deviation of the reaction amplitude \(|M|\) (shown in Fig. 4) from a constant value is due to the FSI.

A similar conclusion is obtained by analysing the \(pp \to pp\eta\) reaction cross section in the same way as illustrated in Fig. 3. Moreover, the experimental data indicate that for kaon production the FSI correction is substantially smaller than for \(\eta\)-meson production. We note that in principle one should account for the FSI between all final particles produced in the reaction \(pp \to p\Lambda K^+\); here we assume that the Λp interaction is much stronger than the \(K^+ p\) and \(K^+ K^+\) interaction, respectively.

Following the original idea of Chew and Low the amplitude \(|A_{FSI}|\) is related to the on mass-shell elastic scattering amplitude \(|A_{el}|\) for the reaction \(\Lambda p \to \Lambda p\), which can be calculated from the corresponding physical cross section in analogy to Eq. (3). The strength of the FSI depends upon the \(\Lambda\)-hyperon momentum in the \(\Lambda p\) center-of-mass system and for fixed excess energy the relative momentum \(q_\Lambda\) extends from zero to its maximal value as shown in Fig. 2b). Thus to calculate the total cross section for the reaction \(pp \to p\Lambda K^+\) at \(\epsilon < 100\) MeV one needs to know the \(\Lambda p\) scattering amplitude for \(0 \geq q_\Lambda \leq 400\) MeV/c.

---

1One should add the amplitude corresponding to the exchange graph.

2Since the resonance properties are fitted to the experimental data, both the resonance model and Eq. (3) should give the same results.
Fig. 4 shows the amplitude $|A_{el}|$ extracted from the experimental data [9] plotted as a function of $q_{\Lambda}$. Actually, there are no data below 50 MeV/c and the experimental results have large error bars. The amplitude $|A_{el}|$, furthermore, can be calculated in the hyperon-nucleon interaction model developed by Holzenkamp, Reuber, Holinde and Speth [7]. Within the Bonn-Jülich approach the $\Lambda p$ elastic scattering cross section is given in the effective-range formalism as

$$\sigma_{\Lambda p\rightarrow\Lambda p} = \frac{\pi}{q_{\Lambda}^2 + (-1/a_s + 0.5r_sq_{\Lambda}^2)^2} + \frac{3\pi}{q_{\Lambda}^2 + (-1/a_t + 0.5r_tq_{\Lambda}^2)^2},$$

(4)

where $a$ is the scattering length and $r$ is the effective range, while the indices $s$ and $t$ stand for singlet and triplet $\Lambda p$ states. The scattering amplitude $|A_{el}|$ was calculated with $a$ and $r$ parameters from Ref. [7] (model $\tilde{A}$) and is shown in Fig. 4 by the dashed line. Actually the effective range approximation is valid at low energies and can not be extended to $q_{\Lambda} > 200$ MeV/c. Following both the low energy prediction from the Bonn-Jülich model and the experimental data we can fit the $\Lambda p$ scattering amplitude as

$$|A_{el}| = C \left[ 1 + \frac{\alpha\beta}{q_{\Lambda}^2 + \alpha^2/4} \right],$$

(5)

with $\alpha = 170$ MeV, $\beta = 130$ MeV and $C = 87$. The result is shown by the fat solid line in Fig. 4.

The FSI amplitude now is proportional to the $\Lambda p$ elastic scattering amplitude, but normalized such that $|A_{FSI}| \rightarrow 1$ at large excess energies $\epsilon$. The solid line in Fig. 4 shows our result calculated with the $|A_{FSI}|$ averaged over the phase space distribution for $q_{\Lambda}$ and the production amplitude $|M_{prod}| = 1.05$ fm. The dashed line in Fig. 4 illustrates the result obtained with the prescription for FSI from Ref. [4, 14] as

$$|A_{FSI}|^2 = \frac{2\beta^2}{(\alpha_s + \sqrt{\alpha_s^2 + 2\mu\epsilon})^2} + \frac{4\beta_t^2}{(\alpha_t + \sqrt{\alpha_t^2 + 2\mu\epsilon})^2},$$

(6)

where $\mu$ is the reduced mass in the $\Lambda p$ system and the parameters $\alpha$ and $\beta$ were evaluated from the scattering length and the effective range for the singlet and spin-triplet $\Lambda p$ interaction [7]. Fig. 4 illustrates a good agreement between the experimental data from COSY [1, 2] and our FSI approach and proves the strong influence of the $\Lambda p$ interaction in the final state.

Actually, the FSI effect can be observed directly by measuring the $pp \rightarrow p\Lambda K^+$ cross section as a function of the momentum $q_{\Lambda}$. Fig. 5 shows this differential cross section calculated by the phase space alone (dashed lines) and with FSI correction (solid lines) for the excess energies $\epsilon$ relevant for COSY-11 and COSY-TOF experiments. The enhancement at low $q_{\Lambda}$ is due to the FSI and is more pronounced for the range of TOF energies.

We conclude, that the $pp \rightarrow p\Lambda K^+$ cross section at energies close to the reaction threshold is strongly affected by the hyperon-nucleon final state interaction. However, this effect is less pronounced as in the $pp \rightarrow pp\eta$ reaction close to threshold since the $\Lambda N$ interaction is weaker than the $pp$ interaction at low relative momenta.

---

3The results are normalized to the experimental total cross section.
Further experimental studies are necessary for the direct measurement of the FSI as a function of the relative momentum $q_{\Lambda}$ as well as more upgrade calculations on the $Y\rho$ interaction, which are under study in Jülich [15].
