Electrospun nanofibers of conducting polyaniline/Al-SnO$_2$ composites for hydrogen sensing applications

Hemlata J. Sharma*, Dipti V. Jamkar, Subhash B. Kondawar

Abstract

In this paper, we report the synthesis and characterization of composites of polyaniline and aluminum doped tin oxide (Al-SnO$_2$/PANI) nanofibers for hydrogen gas sensing application. Al-SnO$_2$/PANI composite nanofibers have been fabricated via electrospinning technique and subsequent calcination procedure. The as-prepared Al-SnO$_2$/PANI composite nanofibers were investigated for structural characterizations by means of SEM, FTIR, UV-VIS and XRD. SEM revealed the nanofibers with the diameter around 200-300 nm formed a non-woven material with highly porous and agglomerated structure. FTIR and UV-VIS spectra revealed the possible incorporation of Al-SnO$_2$ in PANI and confirmed the uniform attachment of PANI on the surface of Al-SnO$_2$ nanostructures. XRD showed peak broadening and the peak positions shift from standard values, indicating presence of aluminum doped tin oxide in nanoparticles form in the polyaniline (PANI) matrix. On exposure to hydrogen gas (1000 ppm), it was found that the nanofibers of Al-SnO$_2$/PANI composite showed high sensitivity at 48 °C with relatively faster response/recovery as compared to pure SnO$_2$ and Al doped SnO$_2$ nanofibers.

Keywords: Nanofibers; Aluminium Doped Tin Oxide; Polyaniline; Nanocomposites; Electrospinning; Hydrogen Sensing.

1. Introduction

Environmental sustainability is a pressing and growing problem due to issues such as climate change, pollution and disturbances associated with biodiversity. A major cause of these environmental threats is pollutants in the atmosphere, Binions and Naik (2013). The gas sensors are highly in demand for detecting, monitoring and controlling the presence of hazardous and poisonous gases in the atmosphere. The fundamental requirements of highly sensitive, selective, stable and fast response gas sensors with economical considerations (multi gas sensor,
small size, low production time and low cost) have lead to extensive research and development in gas sensing area. Generally, these sensors are made of metal oxide semiconductors as sensing materials. Tin oxide (SnO$_2$), compared to the other semiconductor materials based sensor, exhibits better response. Pure tin oxide, SnO$_2$ is a remarkable n-type semiconductor material having wide band gap (~3.6 eV), and by making use of small quantity of dopant into its matrix, thin films of this material find use in several devices such as flat panel displays, gas sensors for the detection of H$_2$, NH$_3$ and NO$_2$ gases, transparent electrodes, photo sensors, photo catalysts, antistatic coatings and solar cells (Tischner et al. 2008, Tai et al. 2007, Qiu et al. 2011, Patil et al. 2014). By doping, its conductivity increases by several orders of magnitude. However, the sensors incorporating doped tin oxide require an elevated temperature (≥ 200°C) for their optimum operation (Berry and Brunet 2008, Hieu et al. 2008). In addition, the sensor operation at elevated temperature itself causes gradual changes in the tin oxide film properties, which in turn deviate gas sensing properties of the device with time (Hu et al. 2003, Kuang et al. 2007). Therefore, it is highly desirable to have sensors, which can operate at room temperature, but having comparable properties with that of tin oxide for gas sensing. Therefore further improvement in methods of material synthesis, surface modifications and sensor fabrication technologies, are required to achieve better performance in tin oxide based gas sensor (Xue et al. 2005, Zhang et al. 2008). Many pure and doped SnO$_2$ have been exposed with high sensing characteristics. Recently, many materials, such as Zn, Pt, Pd and Al have been proved to be effective dopants for the improvements of response or reaction speed or other characteristics of SnO$_2$ (Kolmakov et al. 2005). Al is often chosen because of its properties that improve the oxygen dissociation reaction and its ability to change its oxidation state easily according to the gas environment (Korotcenkov and Cho 2012). In the last few decades, nanofibers have attracted the attention of researchers due to their remarkable micro and nano structural characteristics, high surface area, small pore size, and the possibility of their producing three dimensional structures that enable the development of advanced materials with sophisticated applications. Nanofibers of aluminum (Al) doped SnO$_2$ showed improved sensing properties due to increase in the magnitude of conductivity, but the high operating temperature (280-450°C) of these sensors may be inadequate for measuring high H$_2$ concentrations due to the danger of explosions. The conducting polymers have improved many aspects of the gas sensors especially in lowering the operating temperature to around room temperature. In addition to this, the ability to incorporate specific binding sites into conducting polymers promises the improvement of selectivity and sensitivity (Marsella et al. 1995). Among the various conducting polymers, Polyaniline (PANI) has been investigated as a potential material for H$_2$ gas sensing applications, due to its controllable electrical conductivity, environmental stability and interesting redox properties associated with the chain nitrogen’s (Heeger 2002, MacDiarmid 2002). It is the unique type of conducting polymer in which the charge delocalization can, in principle, offer multiple active sites on its backbone for the adsorption and desorption of H$_2$ gas. Hybridization of metal oxide and conducting polymer could improve the properties of pure metal oxides or conducting polymers based gas sensor (Arora et al. 2014). Since, the Nanofibers of polymeric materials i.e. nanofibers of Al-SnO$_2$/PANI composites have large aspect ratio, large surface area to volume ratio and large porosity, such materials are best for sensing of different gases due to larger absorptive capacity for gas analyte.

The interest in developing solid-state hydrogen gas sensor is due to the fact that presently hydrogen is considered as ‘near- future’ fuel. However, as hydrogen is highly explosive, safety remains a top priority. Hydrogen gas leaks easily from gas lines and systems and is one of the most explosive gases. In fact, a number of problems arise involving the storage of this gas. For this reason, there is a big demand of reliable, flexible and inexpensive H$_2$ gas sensors to prevent accidents due to its leakage, thus, saving lives and infrastructure (Adamyan et al. 2007, Ramesh et al. 2004). Hydrogen gas sensors can quickly and reliably detect hydrogen over a wide range of oxygen and moisture concentrations are not currently available (Ramesh et al. 2004, Yamazaki et al. 2005). At present, commercial hydrogen detectors are not suitable for widespread use, particularly in transportation, because they are too bulky, expensive, and some are dangerous (Yan et al. 2009, Fawcett et al. 2004). From the standpoint of the safety with the global environment, it is necessary today to develop new hydrogen gas sensors working at or near room temperature by using polymeric material at nanolevel. In addition, they should be small, cheap and easy to be implanted into microelectronic IC (Aroutioumian 2007, Shukla et al. 2003). In this work, a high-efficiency hydrogen sensor based on Al-SnO$_2$/PANI composite nanofibers has been fabricated via electrospinning technique. Electrospinning seems to be the simplest and most versatile technique capable of generating (1D) nanostructures.
2. Experimental

2.1. Materials and Methods

SnCl₂·2H₂O, Aniline monomer (distilled under reduced pressure), ammonium peroxydisulphate (APS) and Polyvinyl pyrrolidone (PVP, Mw=1,300,000) were purchased from Aldrich. All supplement chemicals were of AR grade and used as received.

2.2. Fabrication of Al-SnO₂ / PANI composite nanofibers

In a typical procedure, 0.4 g of SnCl₂·2H₂O was dissolved in 0.4 g of as-prepared PANI/CSA from chemical oxidative method. Then, 4.4 g of DMF and 4.4 g of ethanol were mixed in it under vigorous stirring for 30 min. Subsequently, 1% Al(NO₃)₃·9H₂O and 1.0 g PVP were added into the above solution under vigorous stirring for 45 min. The mixture was wrapped into a glass syringe with a needle of 0.5mm in diameter at the tip and was electrified using a high-voltage DC supply. Calcination (400°C in air for 5 h) was performed to remove the organic constituents of PVP and crystallize the Al-SnO₂. For electrospinning, the solution was kept in a vertical syringe with a stainless steel needle having an orifice of 0.5mm. The needle was electrically connected to a positive high voltage. 17 kV was provided between the tip of the spinning nozzle and the collector at a distance of 20 cm and the solution flow rate was kept at 0.4 ml/h, maintained using computer control programmer. Fig. 1 shows the systematic illustration of the whole process of synthesis of nanofibers for hydrogen sensing. The as-prepared nanofibers were characterized by Scanning electron microscopy (SEM, Carl Zeiss Model EVO-18, JSM-7600F), X-ray Diffraction (XRD, PANalytical diffractometer with Cu Kα), UV-Visible spectroscopy (SHIMADZU Spectrophotometer, Model-UV-1800), Fourier transform infrared spectroscopy (FTIR, Bruker Alpha Spectrophotometer) and Hydrogen gas sensing (Keitheley instruments Inc-Model 2000).

3. Results and discussion

3.1. Scanning Electron Microscopy (SEM)

Fig. 2 (a) and 2 (b) shows the typical SEM images of 1% Al-SnO₂ and 1% Al-SnO₂/PANI nanofibers respectively. From SEM micrographs, it is revealed that diameter of as-synthesized 1% Al-SnO₂/PANI nanofibers increased as compared to pristine Al-SnO₂ having the diameter of 200 nm may be due to encapsulation of PANI on the surface of Al-SnO₂ composite, Kondawar et al. (2011). Morphologically, nanofibers of Al-SnO₂ are uniform and fibers of Al-SnO₂/PANI are not, which may be due to change in viscosity and surface tension of the solution prepared using equimass of PANI and SnCl₂·2H₂O. While comparing the porosity from their SEM images, Al-SnO₂/PANI shows more porous structure than that of the pristine Al-SnO₂ nanofibers which causes better sensing properties even at low operating temperature.

![Diagram of the processes involved to prepare nanofibers for H₂ Sensing](image_url)
3.2. **UV-VIS spectroscopy**

UV-VIS spectroscopy was utilized to understand the electronic states of Al-SnO₂ and Al-SnO₂/PANI. Fig. 3(a) shows UV-VIS spectra of 1% Al-SnO₂ and 1% Al-SnO₂/PANI nanofibers. The 1% Al-SnO₂/PANI showed two characteristic bands, one at 404 nm in visible region corresponds to inter ring charge transfer ratio of benzenoid to quinoid moieties showing polaron-π* transition and arises owing to the doping level and the formation of polarons,
MacDiarmid and Epstein (1994) or Jiang et al. (1997) or Kim et al. (2001) and other at 324 nm in UV corresponds to \( \pi-\pi^* \) transition of benzenoid ring and the insertion of Al-SnO\(_2\) in PANI. Optical absorbance studies for 1% Al-SnO\(_2\) also shows the exact value 324 nm of characteristic peak due to the presence of Al-SnO\(_2\) in PANI matrix.

![Fig. 3. (a) UV-VIS spectra and (b) FTIR spectra of 1% Al-SnO\(_2\) and 1% Al-SnO\(_2\)/PANI nanofibers](image)

3.3. Fourier Transform Infrared Spectroscopy (FTIR)

The FTIR spectra of Al-SnO\(_2\) and Al-SnO\(_2\)/PANI nanofibers are shown in Fig. 3(b). Al-SnO\(_2\)/PANI nanofibers shows the peak at 3743 cm\(^{-1}\) associated with the interaction between Al-SnO\(_2\) and PANI by formation of hydrogen bonding between H-N and oxygen of SnO\(_2\). The vibration band seen around 2376 cm\(^{-1}\) has been ascribing to the aromatic C-H vibration. The 1550-1650 cm\(^{-1}\) vibration band is due to the C-N stretching vibration of quinoid rings whereas 1439-1498 cm\(^{-1}\) vibration band arises due to the C-N stretching vibration associated with the benzenoid ring of PANI. In the region close to 1350 cm\(^{-1}\) the peaks are attributed to the presence of aromatic amines present in polyaniline. The 1038 cm\(^{-1}\) vibration band is due to S=O bonding for camphor sulphonic acid and the peaks at around 650-750 cm\(^{-1}\) corresponds to the C-C, C-H bonding mode of aromatic ring and which is due to the Sn-O-Sn stretching. Al-SnO\(_2\) nanofibers shows a broad peak around 600 nm corresponds to the Sn-O-Sn stretching which confirms the formation of Al-SnO\(_2\).

3.4. X-Ray Diffraction

Fig. 4 shows the XRD patterns for 1% Al-SnO\(_2\) and 1% Al-SnO\(_2\)/PANI nanofibers. All the strong diffraction peaks of Al-SnO\(_2\) nanofibers can be perfectly indexed as the tetragonal rutile structure for SnO\(_2\) (ICDD DATA CARD 41-1445), Chang et al. (2008). There is no indication of the presence of any dopants-related diffraction peaks for the Al-doped sample implying the high dispersion or the poor crystallinity of dopant related nanoparticles. In the Al-SnO\(_2\)/PANI nanofibers, most of the peaks are found to be broadened due the polycrystalline effect of PANI as compared to those of Al-SnO\(_2\). The broad peak due to PANI around 26° has been found to be merged with that of Al-SnO\(_2\) at 26.66°. In addition, the reduced intensity of the peaks was observed compared with the XRD of pure Al-SnO\(_2\). The main dominant peaks of Al-SnO\(_2\) were identified at \( 2\theta = 26.66^\circ, 34.18^\circ, 52.3^\circ, 61.34^\circ, 64.4^\circ \) and 65.54° which corresponding to (1 1 0), (1 0 1), (2 1 1), (1 1 2), (3 0 1) and (3 0 2) and the three
strong peaks are assigned to the (1 1 0), (1 0 1) and (2 1 1). PANI deposited on the surface of Al-SnO₂ particles has no effect on the crystallization behaviour of Al-SnO₂ particles in the nanocomposites.

![XRD patterns of 1% Al-SnO₂ and 1% Al-SnO₂/PANI nanofibers](image)

Fig. 4. XRD patterns of 1% Al-SnO₂ and 1% Al-SnO₂/PANI nanofibers

### 3.5. Hydrogen Gas Sensing

In order to systematically investigate the hydrogen gas sensing properties of 1% Al-SnO₂/PANI nanofibers sensor in comparison with the 1% Al-SnO₂, the study of gas sensing response for 1000 ppm with temperature was carried out. A series of experiments at different temperatures was performed to obtain the optimal operating temperature for H₂ detection. Before exposing to the target gas, sensor was stabilized for 6 hour at the room temperature and then the temperature was computerized set when the sensor was exposed to 1000 ppm of hydrogen gas with help of (Keithley instruments Inc. Model 2000). Fig. 5 (a) and Fig. 5 (b) represents the sensitivity and response to H₂ gas respectively for the 1% Al-SnO₂/PANI nanofibers.

It has been observed that there is no appreciable change in the resistance of 1% Al-SnO₂, on exposure to different concentrations of H₂ gas at room temperature. It was found that 1% Al-SnO₂/PANI nanofibers showed better response to H₂ gas as compared to that of 1% Al-SnO₂ reported, Xu et al. (2011). The maximum sensitivity at very low temperature (48 °C) was observed for 1% Al-SnO₂/PANI nanofibers, whereas 1% Al-SnO₂ nanofibers showed the maximum sensitivity at 340 °C for 100 ppm hydrogen gas, Xu et al. (2011). When PANI mixed with Al-SnO₂, then nanocomposite will have synergistic effect of both the components due to which the composite material requires less amount of energy for the electrons to move from valence band to conduction band i.e. the carrier mobility increases. In presence of Al-SnO₂ crystallites, the PANI matrix gets modified structure electronically. Therefore, the resulting material will operate at lower temperatures compared to pure Al-SnO₂. On exposure to H₂ gas, 1% Al-SnO₂/PANI nanofibers film resistance decreased by more than an order of magnitude from its original value, indicating that the electrical resistance of the film is a sensitive parameter in the presence of hydrogen gas. Al-SnO₂ crystallites being an n-type surrounded by p-type PANI molecules make p–n junction like formation locally in composite film. The n-type nature of Al-SnO₂ crystallites annihilate the holes of PANI molecules, near its
boundary making a depletion region, which in turn makes the overall PANI matrix electrically more insulating in nature, Deshpande et al. (2009). On exposing the composite film with hydrogen which can be permeated into the PANI matrix freely, some of the hydrogen molecules might reach into the depletion region, which is surrounding the Al-SnO$_2$ crystallite and act as a dielectric between the PANI and Al-SnO$_2$ border. The depletion region field might polarize the hydrogen molecules, and in turn provide a positive charge to PANI molecules, which can become mobile on its transfer to the central N atom of PANI molecule. This process creates some free holes on PANI molecules, which increase the hopping conductivity of the film, and therefore make the composite film relatively more conducting electrically. Once the process of polarizing the hydrogen molecules by p–n junction like formation is saturated, this mechanism cannot generate additional holes in the composite PANI film and therefore no additional change in the film conductivity occurs even by further addition of hydrogen to it.

![Fig. 5 (a) Sensitivity and (b) Response of 1% Al-SnO$_2$/PANI nanofibers](image)

The response of sensor was monitored in terms of the normalized resistance calculated by $\text{Response} = \frac{R_0}{R_g}$ and the sensitivity factor was monitored in terms of the % sensitivity calculated by % sensitivity $= \frac{\Delta R}{R_0}$. Where $\Delta R$ is the variation in resistance of composite films from baseline after exposure to H$_2$ gas, $R_g$ is the resistance of the sensor in presence of H$_2$ gas and $R_0$ is the initial baseline resistance of the films and as per the definitions of ‘Response time (R$_p$)’ and ‘Recovery time (R$_c$)’ for gas sensing, the values of $R_p$ and $R_c$ for 1% Al-SnO$_2$/PANI nanofibers were estimated to be ~2 sec and ~2 sec respectively while ‘Response time (R$_p$)’ and ‘Recovery time (R$_c$)’ for 1% Al-SnO$_2$ were estimated to be ~3 sec and ~2 sec respectively at 340°C for 100 ppm hydrogen gas.

4. Conclusion

The nanofibers of Al-SnO$_2$ and Al-SnO$_2$/PANI composite with the diameter around 200-300 nm were synthesized successfully via electrospinning technique. The interaction between aluminum doped SnO$_2$ and PANI was confirmed from FTIR, UV-VIS and XRD spectra. The 1% Al-SnO$_2$/PANI hybrid material showed high sensitivity to H$_2$ gas (1000ppm) at an operated temperature 48°C with relatively faster response and recovery. In comparison to the pure SnO$_2$, Al-SnO$_2$ and PANI based sensors reported earlier, the 1% Al-SnO$_2$/PANI sensor in the present study exhibits the faster response and higher sensitivity for hydrogen gas at room temperature.
