(Dated: March 9, 2023)

We investigate how charmonium hadroproduction at fixed-target energies can be used to constrain the gluon distribution in pions. Using nonrelativistic QCD (NRQCD) formulation, the $J/\psi$ and $\psi(2S)$ cross sections as a function of longitudinal momentum fraction $x_F$ from pions and protons colliding with light targets, as well as the $\psi(2S)$ to $J/\psi$ cross section ratios, are included in the analysis. The color-octet long-distance matrix elements are found to have a pronounced dependence on the pion parton distribution functions (PDFs). This study shows that the $x_F$ differential cross sections of pion-induced charmonium production impose strong constraints on the pion’s quark and gluon PDFs. In particular, the pion PDFs with larger gluon densities provide a significantly better description of the data. It is also found that the production of the $\psi(2S)$ state is associated with a larger quark-antiquark contribution, compared with $J/\psi$.

I. INTRODUCTION

The pion, as the lightest QCD bound state, plays an essential role in the nucleon-nucleon interactions over nuclear-size distances [1]. Theoretically, its partonic structure is easier to construct than that of the nucleon. Pion distribution amplitudes and parton distribution functions (PDFs) have been predicted by a number of recent calculations based on the chiral-quark model [2–4], Nambu-Jona-Lasinio model [5], light-front Hamiltonian [6–8], holographic QCD [9–11], maximum entropy method [12, 13], Dyson-Schwinger equations (DSE) [14–24], and lattice QCD [25–37]. In contrast, the partonic structure of pion is much less explored experimentally, due to the absence of a pion target. The present knowledge on the pion PDFs comes primarily from fixed-target pion-induced Drell-Yan (DY) measurements [38]. However, the DY data are mainly sensitive to the valence-quark distributions, leaving the sea and gluon distributions essentially unknown. The sea-quark contributions can in principle be extracted by comparing measurements with the positive and negative pion beams [39], although the existing measurements are scarce and of insufficient statistical accuracy.

The gluon distribution in the pion can be accessed through processes such as prompt-photon production [40], leading-neutron deep-inelastic scattering (DIS) [41, 42] or heavy quarkonia production [43, 44]. Each of these processes has its own advantages and limitations. With the exception of Ref. [45], the pion-induced $J/\psi$ and $\psi(2S)$ production data were not included in the global analysis, possibly reflecting the concern that the production mechanism for charmonium production was not well understood. Significant progress in understanding the $J/\psi$ production mechanism has been made in recent decades, and it is timely to investigate how the charmonium production data can provide useful constraints on the pion PDFs.

The theoretical challenge in describing the charmonium production comes from the treatment of the hadronization of $c\bar{c}$ pairs into a charmonium bound state [46, 47]. This nonperturbative process has been modeled in several theoretical approaches including the color evaporation model (CEM) [48–50], the color-singlet model (CSM) [51–53], and nonrelativistic QCD (NRQCD) [54]. The CEM, although successful for some observables, fails to explain some others observables in charmonium production [55]. Within the more rigorous NRQCD framework, the production of the heavy quark pair is treated perturbatively, whereas its hadronization to a bound state is described in terms of a set of long-distance matrix elements (LDMEs), extracted phenomenologically from the data.

From the experimental perspective, charmonium production has one important advantage: the cross sections are large, between one to two orders of magnitude higher than the DY ones, depending on the experimental conditions. A large number of fixed-target charmonium production experiments have been performed in the past, including experiments with pion beams [56, 57]. These data, collected mostly at CERN or at Fermilab, provide a wealth of additional information on the pion structure, and are expected to shed new light on its gluon distribution.

In this paper we investigate how charmonium production could help to differentiate between the available pion PDFs by imposing further constraints on the gluon distribution function [58, 59]. In the fixed-target energy domain, charmonium production is dominated by the quark-antiquark annihilation ($q\bar{q}$) and gluon-gluon fusion ($GG$) partonic subprocesses. The longitudinal momentum $x_F$-differential cross sections are sensitive to the quark and gluon parton distributions of the colliding hadrons. Since the nucleon PDFs are known with good accuracy, these differential cross sections should provide additional constraints on the pion’s quark and gluon PDFs.

To perform this study, we employ the NRQCD framework, along the lines developed in Ref. [60]. Although limited to leading order (LO), this approach provides an adequate description of the fixed-target $J/\psi$ and $\psi(2S)$ production data and can be used as a tool for accessing the pion PDFs. Our primary goal is to obtain a good phenomenological description of both pion and proton-induced data, and to explore the sensitivity of the results to the pion quark-gluon structure. As-
This paper is organized as follows. In Sec. II, we describe distinctive features of parton densities in four pion PDFs. The NRQCD formalism used for this study is introduced in Sec. III. Section IV briefly describes the $J/\psi$ and $\psi(2S)$ datasets used in the global fit. We present the results of NRQCD calculations using various pion PDFs and the comparison with the charmonium data in Sec. V. Finally we comment on the fit results in Sec. VI and conclude in Sec. VII.

II. PION PDFS

As mentioned before, pion-induced Drell-Yan data are used in all global analyses for constraining the valence-quark distribution of the pion PDFs. Without data from other processes, the sea and gluon distributions can only be inferred through the momentum sum rule and valence-quark sum rule. The two most recent global analyses dedicated to the extraction of the pion PDFs are JAM [61–63] and xFitter [64]. The two groups consider the same DY data, but differ in the choice of the additional processes. The xFitter group makes use of the pion-induced prompt-photon production data, whereas the JAM collaboration includes the leading-neutron DIS cross section measurements instead. The Sutton-Martin-Roberts-Stirling (SMRS) global fit [65] also incorporates the prompt-photon data, but instead of calculating the fit uncertainties, it considers three different options for the gluon and sea contents. Another widely used parametrization is the fit of Gluck-Reya-Vogt (GRV) [66], in which the gluon and sea distributions can only be inferred through the momentum sum rule and valence-quark sum rule. The two most recent global analyses dedicated to the extraction of the pion PDFs are JAM [61–63] and xFitter [64]. The two groups consider the same DY data, but differ in the choice of the additional processes. The xFitter group makes use of the pion-induced prompt-photon production data, whereas the JAM collaboration includes the leading-neutron DIS cross section measurements instead. The Sutton-Martin-Roberts-Stirling (SMRS) global fit [65] also incorporates the prompt-photon data, but instead of calculating the fit uncertainties, it considers three different options for the gluon and sea contents. Another widely used parametrization is the fit of Gluck-Reya-Vogt (GRV) [66], in which the gluon and sea distributions are dynamically generated from the QCD evolution.

We utilize the LHAPDF framework [67, 68] to access these four pion PDFs for our study. The corresponding pion PDF sets are “SMRSP1.LHgrid”, “GRVP11”, “JAM21PionPDFnlo”, and “xFitterPI_NLO_EIG”, respectively. Out of the three possible parametrizations for SMRS, we choose the one in which the sea quarks carry 15% of the momentum at $Q^2=4$ GeV$^2$. Their valence, sea and gluon momentum distributions $x f(x)$ at the scale of $J/\psi$ mass are compared in Fig. 1. Their ratios to SMRS are shown in the bottom panel. Within the range of $x \sim 0.1$–0.8, the valence-quark distributions of SMRS, JAM and xFitter are close to each other, whereas GRV is lower by up to 20%–30%. Not surprisingly, the sea distribution is essentially unknown, as illustrated by the large variations between the four PDFs. The
gluon distributions also show sizable differences; e.g., in the region of $x > 0.2$ the xFitter and JAM distributions are smaller in comparison with SMRS and GRV, by up to a factor of 2-3.

III. HEAVY-QUARK PAIR PRODUCTION AND NRQCD MODEL

Within the NRQCD theoretical framework, the heavy quarkonium production is factorized into production of a heavy-quark pair ($Qar{Q}$) at the parton level, and its subsequent hadronization into quarkonium states. The $Qar{Q}$ production cross section can be calculated perturbatively [69–71], whereas the hadronization probability of the $Qar{Q}$ pair is encoded in the nonperturbative LDME parameters $\langle O_H^{2S+1L_J} \rangle$, depending on the spin, orbital, and total angular momentum quantum numbers, $S$, $L$ and $J$, respectively, and on the color configuration ($\alpha$). Parity, charge conjugation and angular momentum conservation limit the allowed quantum numbers to only a few. The LDMEs are assumed to be universal, i.e., independent of the beam and target hadrons and of the energy scale. The color singlet (CS) LDMEs are typically determined from decay rate measurements using a potential model [72], while the color octet (CO) LDMEs are obtained from a fit to the experimental data.

In NRQCD, the differential cross section $d\sigma/dx_F$ for the production of a charmonium state $H$ ($H = J/\psi, \psi(2S)$, or $\chi_{cJ}$) from the $H$ collisions, where $H$ is the beam hadron ($h = p, \bar{p}$, or $\pi$) and $N$ the target nucleon, is expressed as [73]

$$
d\sigma_H \over dx_F = \sum_{i,j=q,\bar{q},G} \int_0^1 dx_1 dx_2 \delta(x_F - x_1 + x_2) \times \eta^i j [x_1, \mu_F] \eta^N [x_2, \mu_F] \times \sigma^i j [H] [x_1 P_h, x_2 P_N, \mu_F, \mu_R, m_c],
$$

where the indexes $i$ and $j$ run over the type of interacting partons (gluons, quarks and antiquarks), and $\eta^i j [x_1, x_2, \mu_F]$ denotes the hard-QCD production cross section for $c\bar{c}$ pair. The parameter $m_c$ is the charm quark mass; $f^i$ and $f^N$ are the incoming hadron and the target nucleon parton distribution functions, evaluated at their respective Bjorken-$x$ values, $x_1$ and $x_2$. The $\mu_F$ and $\mu_R$ are the factorization and renormalization scales. The Feynman variable $x_F$ and the beam and target parton momentum fractions $x_1$ and $x_2$ are:

$$
x_F = \frac{2p_L}{\sqrt{s}}, \quad x_{1,2} = \frac{x_F^2 + 4M_{c\bar{c}}^2/s}{2} \pm x_F.
$$

Table I. Relationship of LDMEs and the associated orders of $\alpha_s$ to the scattering subprocesses for various charmonium states in the NRQCD framework of Ref. [60]. Here $\Delta_H^H = \langle O_H^{2S+1L_J} \rangle + \frac{4}{m_c^2} \langle O_H^{2S+2L_J} \rangle + \frac{1}{m_c^2} \langle O_H^{2S+1L_J} \rangle$.

| $H$ | $q\bar{q}$ | $GG$ | $qG$ |
|-----|-------------|------|------|
| $J/\psi, \psi(2S)$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ | $\Delta_H^H (\alpha_s^2)$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ |
| $\chi_{c0}$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ | $\Delta_H^H (\alpha_s^2)$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ |
| $\chi_{c1}$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ | $\Delta_H^H (\alpha_s^2)$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ |
| $\chi_{c2}$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ | $\Delta_H^H (\alpha_s^2)$ | $\langle O_H^{2^3S+1^1L_J} \rangle (\alpha_s^2)$ |

The number of independent LDMEs is further reduced by applying the spin symmetry relations [60, 74]:

$$
\langle O_H^{J,\psi,\psi(2S)} \rangle [^3P_J] = (2 J + 1) \langle O_H^{J,\psi,\psi(2S)} \rangle [^3P_J] \quad \text{for} \ J = 2
$$

$$
\langle O_H^{\chi_{cJ}} \rangle [^3S_1] = (2 J + 1) \langle O_H^{\chi_{cJ}} \rangle [^3S_1] \quad \text{for} \ J = 1, 2
$$

$$
\langle O_H^{\chi_{cJ}} \rangle [^3P_J] = (2 J + 1) \langle O_H^{\chi_{cJ}} \rangle [^3P_J] \quad \text{for} \ J = 1, 2
$$

(4)

The LDMEs used in the present work exhibit sensitivity to different elementary scattering subprocesses contributing to the charmonium production. In the cases of $J/\psi$ and $\psi(2S)$ production, the CO $\langle O_H^{2^3S+1^1L_J} \rangle$ LDME is related to the $q\bar{q} \rightarrow Q\bar{Q}$ subprocess, while the $GG \rightarrow Q\bar{Q}$ subprocess is strongly dependent on the $\Delta_H^H$ term. More details on the NRQCD framework used in this work can be found in Refs. [59, 60]. In the following study, the CS $\langle O_H^{2^3S+1^1L_J} \rangle$ LDMEs for $J/\psi$ and $\psi(2S)$ and the CS $\langle O_H^{2^3S+2L_J} \rangle$ and CO $\langle O_H^{2^3S+1^1L_J} \rangle$ LDMEs for $\chi_{cJ}$ are fixed to be $1.16, 0.76, 0.044$ and 0.0032, respectively, which are the values used in Refs. [59, 60].

With the information of LDMEs, the direct production cross sections of $J/\psi, \psi(2S)$ and three $\chi_{cJ}$ states as a function of $x_F$ can be evaluated as shown in Eq.(1). The $J/\psi$ cross section is estimated taking into account the direct production of $J/\psi$ and the feed-down from hadronic decays of $\psi(2S)$ and radiative decays of three $\chi_{cJ}$ states as follows:

$$
\sigma_{J/\psi} = \sigma_{J/\psi}^{direct} + Br(\psi(2S) \rightarrow J/\psi X) \sigma_{\psi(2S)} + \sum_{J=0}^2 Br(\chi_{cJ} \rightarrow J/\psi \gamma) \sigma_{\chi_{cJ}}
$$

(5)
The various branching ratios $Br$ are taken from the PDG 2020 [75]: $Br(\psi(2S) \to J/\psi X) = 61.4\%$, $Br(\chi_{c0} \to J/\psi \gamma) = 1.4\%$, $Br(\chi_{c1} \to J/\psi \gamma) = 34.3\%$, and $Br(\chi_{c2} \to J/\psi \gamma) = 19.0\%$.

In the present analysis we use the convention of charm quark mass, factorization and renormalization scales in Ref. [60] for fixed-target hadroproduction of charmonium: $m_c = 1.5$ GeV/$c^2$ and $\mu_F = \mu_R = 2m_c$. The uncertainties associated with this choice are evaluated by changing the reference scale from $m_c$ to $3m_c$. The nucleon PDFs are taken from CTEQ14nlo [76]. For the lithium, beryllium, silicon, gold and tungsten targets, the nuclear EPPS16 PDFs [77] are used.

IV. OVERVIEW OF DATA USED

The present analysis is based on pion and proton-induced total and differential cross sections for $J/\psi$ and $\psi(2S)$ production, and on the differential $R_\psi(x_F) = \sigma_\psi(2S)(x_F)/\sigma_{J/\psi}(x_F)$ ratios. The total cross sections for the pion-induced data were taken from the compilations made in Refs. [56] and [57]. The proton-induced total cross sections and ratios were taken from Ref. [74]. The proton-induced values for $R_\psi$ from HERA-B [78] and NA38 [79] and the pion-induced ones from WA92 [80] and WA39 [81] were added to the selection. The $x_F$-differential cross sections for pion-induced $J/\psi$ production [82–87] and $\psi(2S)$ production [82] were selected according to the targets used: hydrogen, lithium and beryllium. Datasets with heavier targets were not included. The same criterion was applied to the proton-induced $J/\psi$ production [83, 84]. The $R_\psi(x_F)$ ratios were taken from Ref. [88] for the pion-induced production and from Refs. [78, 89–91] for the proton-induced one. Assuming that nuclear effects are identical for both charmonium states, no restriction on the target employed was applied.

The datasets with $x_F$ dependent measurements are listed in Table II. In terms of pion-induced (proton-induced) data sets, there are 8 (2) for $J/\psi$ production, 2 (0) for $\psi(2S)$ production and 1 (4) for $R_\psi(x_F)$. In total, there are 164 and 82 data points for the pion-induced and proton-induced data, respectively. The beam momenta of the datasets cover the range of 39.5–515 GeV/$c$, corresponding to $\sqrt{s}$ values ranging from 8.6 to 31.1 GeV.

V. RESULTS OF NRQCD CALCULATIONS

A. Reference NRQCD calculations

Before performing a fit to the data listed in Table II to obtain the best-fit LDMEs for the four pion PDFs, we first carry out NRQCD calculations using the LDMEs found in a recent study [59], where only the pion and proton total cross section data were fitted. The values of the LDMEs, obtained separately for each pion PDF, are listed in Table III. We then compare the results of the NRQCD calculations for the $x_F$ dependent charmonium production cross sections with the data listed in Table II and shown in Fig. 2. We call these “Reference NRQCD calculation” (REF), which provides the reference information to be compared with that obtained later from a fit to the $x_F$-dependent cross section data. Note that Fig. 2 is for the SMRS pion PDFs, and similar figures for the other three pion PDFs can be found in the Supplemental Material [92].

The total $\chi^2/ndf$, as well as the $\chi^2/ndp$ (ndp denotes “number of data points”) for individual pion or proton datasets, are listed in Table III under the label “REF”. Table III shows that the reduced $\chi^2/ndf$ for “REF” are quite large, suggesting that the LDMEs deduced from the fit to total cross section data are not optimal for describing the $x_F$-dependent data. A further investigation shows that a significant contribution to the overall $\chi^2$ comes from the absolute normalization of the measured cross sections relative to the NRQCD calculations. Despite the poor agreement between the data and the calculation, it is interesting to note that calculations using the SMRS and GRV pion PDFs are in a better agreement with the data than the JAM and xFitter PDFs.

B. NRQCD fits

We now proceed to a refined determination of the color-octet ($O^H_{1}[^3S_{1}]$) and $\Delta_{1}^{H}$ LDMEs for $J/\psi$ and $\psi(2S)$ production by fitting the $x_F$ differential cross sections and $R_\psi(x_F)$ ratios for proton and pion beams. To avoid double counting, total cross sections data that result from an integration over the associated differential cross sections are not included in the fit. We note that the NRQCD calculations do not require a normalization factor, as they predict absolute cross sections. However, the experimental $x_F$-dependent $J/\psi$ and $\psi(2S)$ cross sections are associated with experimental normalization uncertainties $\delta_x$, as quoted in Table II. An attempt to fit the data without taking into account the normalization uncertainties only marginally reduces the total $\chi^2/ndf$. In order to take into account these uncertainties, a normalization parameter $F$ is added for each of the $x_F$-differential datasets. Accordingly, a penalty term of $((F - 1)/\delta_F)^2$ is included in the calculation of the overall $\chi^2$. To avoid unrealistic values of $F$, we limit the deviation of $F$ from 1.0 to be less than 2 $\delta_F$. The results of this approach are labeled as “FIT II” below.

Figure 2 shows the new fit to the data for $x_F$-differential data and ratios using the SMRS pion PDFs. The newly-determined LDMEs parameters are shown in Table III. Except for the $J/\psi$ data of WA11, the new NRQCD fit provides a reasonably good description of data for both pion and proton beams. Table III shows that for all four pion PDFs and for nearly all datasets the individual $\chi^2/ndf$ are significantly improved. The displayed yellow uncertainty bands result from the scale and charm mass variations of charm quark mass $m_c$ of 1.4 and 1.6 GeV/$c^2$ at $\mu_F = \mu_R = 2m_c$, and $\mu_F = \mu_R = = 1$ and 4 $m_c$ at $m_c = 1.5$ GeV/$c^2$. The uncertainty is evaluated by the square root of the sum of squares of the cross section difference due to the individual variation. The corresponding LDMEs are obtained from a new global fit for each configuration. The uncertainty bands are relatively small and do not

TABLE III. Results of the NRQCD calculation using the reference values of the LDMEs (columns labeled “REF”) and of the fit of the LDMEs to the differential cross sections (columns “FIT”). The upper part of the table gives the values of the reduced \(\chi^2/\text{ndf}\) of the entire dataset and the \(\chi^2\) divided by the number of data point (ndp) for the pion-induced and proton-induced datasets separately. The subscript \(x_F\) or \(\sqrt{s}\) for \(\chi^2/\text{ndp}\) refers to \(x_F\)-dependent data or \(\sqrt{s}\)-dependent \(x_F\)-integrated data. The lower part of the table displays the values of the reference and fitted LDMEs for SMRS, GRV, JAM and xFitter pion PDFs. All LDMEs are in units of \(\text{GeV}^3\).

introduce an essential change in the quality of data description. The systematic studies are further discussed in Sec. V F. Similar figures for GRV, JAM and xFitter are available in the Supplemental Material [92].

Table III also lists the \(\chi^2\) values for both the “REF” and “FIT” calculations. The \(\chi^2/\text{ndp}\) and the fitted normalization factors for each dataset are summarized in Table IV. The improved description of the differential cross sections is also confirmed by the overall \(\chi^2_{total}/\text{ndf}\) and the \(\chi^2/\text{ndp}\) values for various datasets. The \(\chi^2/\text{ndp}\) of the pion-induced \(x_F\) data sets, \(\chi^2_{ndp}^{J/\psi}\), are 1.8, 2.4, 5.9 and 4.5 for the SMRS, GRV, JAM and xFitter PDFs, respectively, an improvement of about a factor of three over that of “REF”. As expected, the \(\chi^2/\text{ndp}\) of the proton-induced \(x_F\) datasets, \(\chi^2_{ndp}^{\psi(2S)}\), are of similar values, around 2.0 for all four pion PDFs. In contrast, the \(\chi^2/\text{ndp}\) of the integrated cross sections \(\chi^2_{ndp}^{[3S_1]}\) are now larger since these data are not included in the global fit.

Table III also shows the newly fitted LDMEs. In comparison with the “REF” calculation, the “FIT” results give smaller \(\langle O_8^{J/\psi}\rangle_{[3S_1]}\) values for both SMRS and GRV PDFs, while the corresponding \(\Delta_{J/\psi}^{J/\psi}\) LDMEs are slightly larger. For the JAM and xFitter PDFs, the “REF” and “FIT” LDMEs remain consistent within their uncertainties. The \(\chi^2/\text{ndp}^{J/\psi}_{x_F,\sqrt{s}}\) have a mild dependence on the pion PDFs, only through the correla-
FIG. 2. The $x_F$-dependent cross sections for $J/\psi$ and $\psi(2S)$ production and $R_{\psi}(x_F)$ ratios in $\pi^-N$ and $pN$ interactions, following the order given in Table II. The symbol and value in parenthesis denote the particle type and momentum of beam. The solid red and dotted black curves represent the NRQCD results of SMRS pion PDFs from the fit described in the text ("FIT") and from the calculation using the LDMEs obtained in Ref. [59] ("REF"), respectively. The values of $\chi^2$ divided by the number of data point (ndp) for each dataset are also shown. The yellow bands represent the cross section uncertainties associated with the scale and charm quark mass systematic variations.

A comparison of the $J/\psi$ production data and the NRQCD calculations in terms of the subprocess contributions has been made for all of the datasets included in the fit. Irrespective of the pion PDFs, the relative weighting of $q\bar{q}$ and $GG$ shows a strong energy dependence. At the lowest energy, the $q\bar{q}$ term provides the major contribution to the cross section, similar to the DY production, while the $GG$ contribution is dominant at the highest beam energies. A global analysis of charmonium datasets with a wide range of beam energy could simultaneously constrain both pion’s valence quark and gluon distribu-

C. Differential cross sections for $J/\psi$

In NRQCD, the relative weighting between $q\bar{q}$ and $GG$ subprocesses is set by a convolution of the pQCD partonic cross sections, the associated parton densities, and the LDMEs. The $F$ factor does not modify the shape of $d\sigma/dx_F$. Therefore, adequate shapes of $d\sigma/dx_F$ distributions of individual $GG$ and $q\bar{q}$ contributions from NRQCD calculations are required to achieve a reasonable description of the data, particularly for $x_F > 0.5$. Since the partonic cross sections and the nucleon PDFs involved in the calculations of the cross sections remain the same, the variation of the results originates from the difference in the pion PDFs and the LDMEs.
Each of the four pion PDFs. This comparison is illustrated in Figs. 3 and 4 for the data with pion beam momenta of 39.5 GeV/c [87] and 515 GeV/c [82]. The χ²/ndf values are displayed in the plots.

At the lowest beam momentum of 39.5 GeV/c (Fig. 3), the q̅q subprocess provides the largest contribution to the cross section over the whole x_F region. The GG contribution is much reduced, so that the shape of the x_F distribution is essentially determined by the shape of the q̅q contribution. Since the pion valence-quark distribution is well determined from...
the DY data, good $\chi^2$/ndf values are obtained for the four PDFs. Nevertheless, the agreement with the data is less satisfactory for JAM. Figure 3 also suggests that future $J/\psi$ data at negative $x_F$ with low beam energies could further constrain the pion valence-quark distribution at lower $x$.

At the highest beam momentum of 515 GeV/c, where the $GG$ component becomes dominant, Fig. 4 shows that SMRS and GRV are favored over JAM and xFitter. The fraction of the $GG$ component is maximized around $x_F = 0$, corresponding to the gluon distribution $G_g(x)$ around $x \sim 0.1$–0.2. As a result of the rapid drop of the $G_g(x)$ toward $x = 1$, the $GG$ contribution quickly decreases at large $x_F$. In contrast, the $q\bar{q}$ contribution has a slower fall-off toward high $x_F$ because of a relatively strong pion valence antiquark density, in comparison with the gluon one, at large $x$. Consequently, the $q\bar{q}$ contribution has a broader $x_F$ distribution than that of the $GG$ contribution and the relative importance of $q\bar{q}$ rises at the large $x_F$ region. The ratio of $q\bar{q}$ to $GG$ shows a strong $x_F$ dependence, making the $x_F$-differential cross sections at high energies particularly sensitive to the shape of pion $G_g(x)$.

Similar conclusions can be drawn for the intermediate energies used in this analysis. The corresponding figures are available in the Supplemental Material [92]. As a general observation, the $q\bar{q}$ and $GG$ contributions have quite similar strengths for the fits with SMRS and GRV, whereas the $q\bar{q}$ contribution is the dominant component for the fits with JAM and xFitter. In terms of $\chi^2$/ndf, the data show a slight preference for GRV and SMRS.

### D. Differential cross sections for $\psi(2S)$ and the $R_\psi(x_F)$ ratios

![Graphs showing differential cross sections for $\psi(2S)$ production with various PDFs](image)

FIG. 5. Same as Fig. 4 for $\psi(2S)$ production with a 515-GeV/c $\pi^-$ beam [82].

Additional information on the charmonium production mechanism can be obtained by comparing the production of the two charmonium states, $J/\psi$ and $\psi(2S)$. The strengths of their $q\bar{q}$ and $GG$ subprocesses are controlled by the associated LDMEs. In comparison with the $J/\psi$, the smaller cross section for the $\psi(2S)$ production implies also smaller LDMEs. The fitted LDMEs are indeed smaller, but interestingly, not in the same proportion. As shown in Table III, the values of the $(\langle c\bar{c}|O^{[2S]}_8|c\bar{c}\rangle)$ LDMEs for $\psi(2S)$ are smaller than that for $J/\psi$ by a factor of two. In contrast, the $\Delta_F^{[2S]}$ values for $\psi(2S)$ are an order of magnitude smaller. This is illustrated in Fig. 5 for the E672/E706 $\psi(2S)$ data taken at 515 GeV/c [82]. In comparison with the production of $J/\psi$ at the same energy (Fig. 4), the $q\bar{q}$ contribution is greatly enhanced in $\psi(2S)$ production. Figure 5 shows that this observation is valid for all pion PDFs, and the $q\bar{q}$ term is even dominant for JAM and xFitter. For the fit with the SMRS pion PDFs around $x_F = 0$, the $q\bar{q}$ component accounts for about 15% of the direct part (feed-down excluded) of the $J/\psi$ cross section. Its fraction rises to nearly 30% for $\psi(2S)$. Obviously, the increase of the $q\bar{q}$ term is compensated by a decrease of the $GG$ term. This significant difference between the two charmonium states can only be partially explained by the larger $\psi(2S)$ mass. Its full understanding would require further investigations.

![Graphs showing $R_\psi(x_F)$ ratios for $J/\psi$ and $\psi(2S)$ production](image)

FIG. 6. The $\psi(2S)$ to $J/\psi$ cross section ratios $R_\psi(x_F)$ for $J/\psi$ and $\psi(2S)$ production with a 252-GeV/c $\pi^-$ beam [88]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The ratios of total cross sections and individual $R_\psi^{[2S]}(x_F)$ and $R_\psi^{GG}(x_F)$ contributions are denoted as solid black, dashed blue, and dotted red lines, respectively.

The observations above are consistent with the measurements of the $\psi(2S)$ to $J/\psi$ ratios, $R_\psi(x_F)$. The largest statistics on $R_\psi(x_F)$ have been collected by the E615 experiment
for an incident pion momentum of 252 GeV/c [88]. The data are compared to the NRQCD fits with each of the four pion PDFs in Fig. 6. The \( R_{\psi}(x_F) \) shows a strong \( x_F \) dependence and this suggests that the relative weights of the individual subprocesses \( \bar{q}q \) and \( GG \) components in \( J/\psi \) and \( \psi(2S) \) production are distinctly different. We note that the CEM models predict an \( x_F \)-independent \( R_{\psi}(x_F) \) [78], since the fractions of \( \bar{q}q \) and \( GG \) components are identical for each charm resonance state. In NRQCD, an \( x_F \)-dependent \( R_{\psi}(x_F) \) is possible due to different LDMEs associated with the \( \bar{q}q \) and \( GG \) channels in producing \( J/\psi \) and \( \psi(2S) \). The pronounced \( x_F \) dependence of \( R_{\psi}(x_F) \) in Fig. 6 clearly disfavors the CEM model.

As shown in Figs. 4 and 5, the \( \bar{q}q \) subprocess gives a significantly broader \( x_F \) distribution than the \( GG \) subprocess. This is caused by the slower fall-off of the valence-quark distribution than the gluon distribution toward \( x = 1 \). Therefore, the pronounced rise in the \( R_{\psi}(x_F) \) data at forward \( x_F \), shown in Fig. 6, clearly indicates that the \( \bar{q}q \) subprocess is more important for the \( \psi(2S) \) production than for the \( J/\psi \) production.

It is also instructive to examine the \( x_F \) dependence of \( R_{\psi}(x_F) \) from the \( \bar{q}q \) and \( GG \) subprocesses separately. In Fig. 6, the dashed blue and dotted red curves correspond, respectively, to

\[
R_{\psi}^{\bar{q}q}(x_F) = \frac{\sigma_{\psi(2S)}^{\bar{q}q}(x_F)}{\sigma_{J/\psi}^{\bar{q}q}(x_F)}, \quad R_{\psi}^{GG}(x_F) = \frac{\sigma_{\psi(2S)}^{GG}(x_F)}{\sigma_{J/\psi}^{GG}(x_F)},
\]

where the superscripts \( \bar{q}q \) and \( GG \) denote the two subprocesses. Neglecting the tiny contribution from the \( qG \) subprocess, one can then obtain

\[
R_{\psi}(x_F) \equiv \frac{\sigma_{\psi(2S)}(x_F)}{\sigma_{J/\psi}(x_F)} = [A(x_F)R_{\psi}^{\bar{q}q}(x_F) + B(x_F)R_{\psi}^{GG}(x_F)],
\]

where

\[
A(x_F) = \frac{\sigma_{\psi(2S)}^{\bar{q}q}(x_F)}{\sigma_{J/\psi}^{\bar{q}q}(x_F)} \quad \text{and} \quad B(x_F) = \frac{\sigma_{\psi(2S)}^{GG}(x_F)}{\sigma_{J/\psi}^{GG}(x_F)}
\]

have the property \( 0 \leq A(x_F) \leq 1 \) and \( 0 \leq B(x_F) \leq 1 \). It follows that \( R_{\psi}(x_F) \) must be bounded by \( R_{\psi}^{GG}(x_F) \) and \( R_{\psi}^{\bar{q}q}(x_F) \) in Fig. 6. As shown in Fig. 6, the \( R_{\psi}(x_F) \) data largely fall within these two bounds for calculations with the SMRS and GRV PDFs, while a large fraction of the data are outside of these bounds for the calculations using the JAM and xFitter PDFs. The striking contrast between the SMRS/GRV and the JAM/xFitter PDFs in their ability to describe the \( R_{\psi}(x_F) \) data in Fig. 6 illustrates the advantages of the \( R_{\psi}(x_F) \) data in constraining the pion PDFs. We also note that none of the pion PDFs can explain the sharp rise of the \( R_{\psi}(x_F) \) data beyond \( x_F = 0.8 \). This incompatibility at large \( x_F \) could be due to either higher-twist effects [88] or higher-order QCD processes that are beyond the present leading-order NRQCD analysis.

Our analysis also shows that fixed-target charmonium production data are particularly sensitive to the color octet contribution to the cross section. This is illustrated in Fig. 7 which displays the decomposition of the \( J/\psi \) \( x_F \)-dependent cross sections from the E705 experiment [83] into color octet and color singlet contributions. The CO contribution plays a dominant role in the \( J/\psi \) production across the entire \( x_F \) range, and this observation is valid for any of the four pion PDFs. Further information can be obtained by separating the CO contribution into \( GG \) and \( \bar{q}q \) components. Only the CO \( GG \) component, controlled by the \( \Delta^H \) LDME, is displayed. For the SMRS and GRV pion PDFs it provides the largest part of the CO contribution. In contrast, its relative magnitude is significantly reduced for the JAM and xFitter PDFs, an observation that is in line with their smaller gluon distributions.

**E. Integrated cross sections**

Because of the presence of valence antiquarks in the pion, the \( \bar{q}q \) and \( GG \) subprocesses to the \( J/\psi \) production with proton and pion beams have different contributions to the integrated cross sections. In the production with a proton beam the \( GG \) contribution is dominant across all center-of-mass energies \( \sqrt{s} \) except near threshold. With pion beams the \( \bar{q}q \) contribution is significantly enhanced. It dominates at low energies, with \( GG \) contribution gradually becoming important as \( \sqrt{s} \) increases.

Our analysis of the differential cross sections shows that the relative contributions of the \( \bar{q}q \) and \( GG \) subprocesses in the production of \( J/\psi \) and \( \psi(2S) \) differ considerably. The same conclusion can be drawn from the integrated cross sec-

The data for $J/\psi$ and $\psi(2S)$ production are compared to the results of NRQCD calculations with the SMRS pion PDFs and the “FIT” LDMEs in Table III. The total cross section and its $q\bar{q}$ and $GG$ contributions are denoted as solid black, dashed blue and dotted red lines, respectively. The yellow bands represent the cross section uncertainties associated with the scale and charm quark mass systematic variations.

The plots for GRV, JAM and xFitter pion PDFs are displayed. The plots for GRV, JAM and xFitter pion PDFs are provided in the Supplemental Material [92]. All these observations confirm our previous conclusion: the $q\bar{q}$ contribution plays a much more important role in the $\psi(2S)$ production, compared to $J/\psi$.

F. Systematic studies

So far only the uncertainties associated with the parametrizations of JAM and xFitter PDFs have been taken into account. Our results are also sensitive to the NRQCD input parameters and to the choice of the nuclear PDFs. We have checked that fits performed with the nCTEQ15 [93] parametrization instead of EPPS16 result in negligible differences. Fits with the factorization/renormalization scale parameter $\mu_R$ set to 1, 2, and 4 $m_c$, with $m_c = 1.4, 1.5,$ and 1.6 GeV/$c^2$, have also been made. The values of the total $\chi^2/\text{ndf}$ do not vary much: they remain nearly unchanged between $\mu_R = m_c$ and $\mu_R = 4m_c$ at $m_c = 1.5$ GeV/$c^2$. The effect on the values of the LDMEs is more important. For both $J/\psi$ and $\psi(2S)$ the fitted LDMEs increase by nearly a factor of four when $\mu_R$ increases from $m_c$ to $\mu_R = 4m_c$. Nevertheless, the shape and the magnitude of the final cross section remain nearly unchanged, as illustrated in Fig. 9 for the fit with the SMRS PDFs. The relative contributions of the $q\bar{q}$ and $GG$ subprocesses for the three values of $\mu_R$ are only
FIG. 9. The NRQCD results with variation of charm quark mass $m_c$ and renormalization scale $\mu_R$, compared with the $d\sigma/dx_F$ data of $J/\psi$ production off the beryllium target with a 515-GeV/c $\pi^-$ beam from the E672/E706 experiment [82]. The pion PDFs used for the calculation is SMRS. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red and dot-dashed green lines, respectively. The charm quark mass $m_c$, factorization scale $\mu_F$, and renormalization scale $\mu_R$ used for the NRQCD calculation as well as the fit $\chi^2$/ndf are displayed in each plot.

slightly modified. The charm quark mass correlates with the LDMEs in the partonic cross sections. Consequently, the variation of $m_c$ around its nominal value affects the values of the best-fit LDMEs and the overall quality of fits remains stable. The systematic studies with GRV, JAM and xFitter pion PDFs lead to results fully consistent with these conclusions. The corresponding figures and tables are available in the Supplemental Material [92].

The overall $\chi^2$/ndf for the pion-induced $J/\psi$ and $\psi(2S)$ $x_F$-dependent data versus different choices of scale and $m_c$ for four pion PDFs are shown in Fig. 10. The $\chi^2$/ndf values of SMRS and GRV remain consistently better than those of JAM and xFitter. The systematic variation of the scale and mass parameters do not change the preference of the data for GRV and SMRS.

In addition, the theoretical uncertainties corresponding to the variations of $m_c$ from 1.4 to 1.6 GeV at $\mu_R = 2 m_c$, and those of $\mu$ from $m_c$ to 4 $m_c$ at $m_c = 1.5$ GeV/c$^2$ with the fixed LDMEs labeled as “FIT” in Table III for the total and differential $x_F$ cross sections are displayed as yellow bands in Figs. 22 and 23, respectively, in the Supplemental Material [92]. Compared to Figs. 2 and 8, the uncertainty bands in these two additional figures are significantly larger, with the overall $\chi^2$/ndf rising by a factor of 20 to 50. We note however that the increase in $\chi^2$ is primarily due to the changes in the overall normalization, common to all pion PDFs, while the shapes of the $x_F$ dependence are largely preserved. This suggests that the ability to discriminate various pion PDFs, based on their predicted shapes of the $x_F$ distributions, is insensitive to the choice of $m_c$ and $\mu$.

VI. DISCUSSION

Our analysis shows that the $x_F$-dependent proton and pion-induced $J/\psi$ and $\psi(2S)$ production data can be simultaneously described within the NRQCD framework. The results exhibit a strong dependence on the pion PDFs and particularly on the gluon distribution. The conclusions drawn here
fully corroborate the results obtained previously [58] using the more phenomenological color evaporation model. The similarity between the results of the two studies indicate that our main findings are quite independent of the charmonium production models.

We note that our analysis is performed in leading order only and in the region of small $p_T$, in which a proof of factorization is still lacking. Our work is based on the assumption adopted in Refs. [60] and [74] that NRQCD can lead to a satisfactory description of proton-induced charmonium production at fixed-target energies. In order to evaluate the theoretical uncertainties associated with these limitations, we also investigated the sensitivity of the results to the NRQCD input parameters. Varying the scale and the charm mass parameters within the commonly accepted ranges leads to the error bands shown in Figs. 2 and 8. The calculations with each of the four pion PDFs are all modified consistently, preserving the independence already observed for the best fits.

The values of the color-octet LDMEs, resulting from the fits to the data may contain model uncertainties, although they provide a good description of the data. The formalism used is limited to LO and is able to determine individually the CO ($\langle O^{J/\psi}_{8}^{3[S_1]} \rangle$) LDMEs for $J/\psi$ and $\psi(2S)$ only. The $\Delta_{J/\psi}^{8}$ and $\Delta_{\psi}^{(2S)}$ terms combine each three additional color octet LDMEs. Furthermore, most of the data included in the analysis have transverse momenta $p_T$ smaller than 3 GeV/c. This is in sharp contrast with most of the available LDMEs that result from fits at much larger energies and for transverse momenta $p_T$ larger than 5 GeV/c [94] and often even larger than 10 GeV/c [95]. Assuming the approximate universality of the LDMEs, a comparison with the published values remains qualitative and can be solely used as an indirect criterion for the significance of our results [96].

For the fits on the $J/\psi$ data sample, the $\langle O^{J/\psi}_{8}^{3[S_1]} \rangle$ values obtained, e.g. $(2.59 \pm 0.23) \times 10^{-2}$ GeV$^3$ for the SMRS pion PDFs, are nearly an order of magnitude larger than some of the published LDMEs [97, 98]. Yet, they are only a factor of 2.5 larger than the values of $(1.0 \pm 0.3) \times 10^{-2}$ GeV$^3$ reported in Ref. [99] derived from data on $\eta_c$ production using spin symmetry relations and $(1.1 \pm 1.0) \times 10^{-2}$ GeV$^3$ obtained in Ref. [95] from fits to Tevatron and LHC data. For the $\psi(2S)$, the fitted $\langle O^{\psi(2S)}_{8}^{3[S_1]} \rangle$ LDME with the SMRS pion PDFs has a value of $(1.32 \pm 0.90) \times 10^{-2}$ GeV$^3$, about a factor of four larger than the values quoted in Refs. [100, 101] and more recently in Ref. [102]. A value with a different sign has also been reported [103]. The comparison of our $\Delta_{J/\psi}^{8}$ and $\Delta_{\psi}^{(2S)}$ LDMEs with the individual CO ($\langle O_{8}^{J/\psi}^{3[S_0]} \rangle$) values is only indicative. The $\Delta_{J/\psi}^{8}$ value is compatible with the values derived in Refs. [95, 97–99]. The $\Delta_{\psi}^{(2S)}$ LDME is also inside the range defined by the values quoted in Refs. [100–102]. Within the systematic uncertainties associated with the fits and given the assumptions made, the comparison can be considered satisfactory, providing an indirect support for the present analysis.

Our analysis is performed using a leading-order NRQCD framework only. The results obtained may vary if a more advanced NRQCD formalism with higher order terms is applied. In addition, for most of the fixed-target data considered here, the mean transverse momenta are smaller than the $J/\psi$ mass. Inclusion of higher-order corrections could therefore provide a better description, but probably would not change the general conclusions. The analysis has been also limited to data taken with only light targets. A large amount of data of $x_F$-differential cross sections with heavier targets have been collected in the past. These data could be included in a more complete analysis if the energy loss effects [104] responsible for the suppression of the charmonium cross section in hadron-nucleus collisions are reliably accounted for.

VII. CONCLUSION

We have analyzed fixed-target experimental cross sections for $J/\psi$ and $\psi(2S)$ production using the NRQCD framework. To minimize nuclear matter effects, only data on hydrogen, lithium and beryllium targets were selected. Heavier targets were only considered for the data on the $J/\psi$ to $\psi(2S)$ ratios. Assuming the universality of the NRQCD approach, both pion and proton-induced datasets were included in the analysis. Fits to the individual $x_F$-differential cross sections and their ratios have been made, using four different pion PDF parametrizations. The proton data, although not directly sensitive to the pion PDFs, enrich the selection and contribute to the stability of the final results.

A simultaneous fit to all pion and proton datasets has been achieved. The results of these common fits show that the relative fractions of the $q\bar{q}$ and $GG$ contributions to the cross sections strongly depend on the beam particle, on its incoming energy and on the $x_F$ region considered. A strong dependence on the pion PDF parametrization used is observed and particularly on the magnitude of the pion gluon distribution. The results indicate a clear preference for parametrizations with larger gluon distributions at relatively large $x$. Good agreement with the data is obtained with the SMRS and GRV PDFs. The fits with the recent JAM and xFitter parametrizations turn out to show much larger deviations for most of the datasets.

The comparison between the results for $J/\psi$ and $\psi(2S)$ production leads to an important new observation: the strengths of the $q\bar{q}$ and $GG$ contributions to these two charmonium states are – unexpectedly – quite different. The $q\bar{q}$ component of the $\psi(2S)$ cross section is, proportionally, few times larger than the $q\bar{q}$ component of the $J/\psi$ cross section. This interesting feature is confirmed for both differential and integrated cross sections and for both pion and proton beams. The production of $\psi(2S)$ appears to be more sensitive to the pion’s valence quark distribution than that of $J/\psi$. This observation could be relevant for a better understanding of the charmonium production mechanism.

In the kinematical domain of the available fixed-target data – relatively small center-of-mass energy and therefore small transverse momenta – the theoretical uncertainties could be substantial. A proof of factorization is still lacking and additional higher-order corrections may play a role. Conversely, the conclusions drawn rely on a simultaneous study of the pion and proton-induced cross sections and ratios, both $x_F$-
These data will be important in providing better knowledge of the pion PDFs. For the longer-term electron-ion collider projects in U.S. and China, the pion as well kaon structures are planned to be explored using the tagged DIS process [108–110].

The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 5. Differential cross sections for $J/\psi$ production with a 280-GeV/c $\pi^- \bar{\pi}^+$ beam from the NA3 experiment [84]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively. The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 6. Differential cross sections for $J/\psi$ production with a 200-GeV/c $\pi^-$ beam from the NA3 experiment [84]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively. The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 7. Differential cross sections for $J/\psi$ production with a 190-GeV/$c$ $\pi^-$ beam from the WA11 experiment [85]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively. The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 8. Differential cross sections for $J/\psi$ production with a 150-GeV/c $\pi^-$ beam from the NA3 experiment [84]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively. The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 9. Differential cross sections for $J/\psi$ production with a 125-GeV/$c$ $\pi^-$ beam from the E537 experiment [86]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively. The uncertainty bands associated with JAM and xFitter PDFs are also shown.
FIG. 10. The $\psi(2S)$ to $J/\psi$ cross section ratios $R_\psi(x_F)$ for $J/\psi$ and $\psi(2S)$ production with a 920-GeV/c proton beam from the HERA-B experiment [78]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The ratios of total cross sections and individual $R_\psi(x_F)$ and $R_{GG}(x_F)$ contributions are denoted as solid black, dashed blue, and dotted red lines, respectively.
FIG. 11. The $\psi(2S)$ to $J/\psi$ cross section ratios $R_{\psi}(x_F)$ for $J/\psi$ and $\psi(2S)$ production with a 450-GeV/c proton beam from the NA50 experiment [89]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The ratios of total cross sections and individual $R_{\psi}^q(x_F)$ and $R_{\psi}^{GG}(x_F)$ contributions are denoted as solid black, dashed blue, and dotted red lines, respectively.
FIG. 12. The $\psi(2S)$ to $J/\psi$ cross section ratios $R_{\psi}(x_F)$ for $J/\psi$ and $\psi(2S)$ production with a 450-GeV/$c$ proton beam from the NA50 experiment [89]. The data are compared to the NRQCD fit results for the SMRS, GRV, xFitter, and JAM PDFs. The ratios of total cross sections and individual $R_{\psi}(x_F)$ and $R_{\psi}^{GG}(x_F)$ contributions are denoted as solid black, dashed blue, and dotted red lines, respectively.
FIG. 13. The $\psi(2S)$ to $J/\psi$ cross section ratios $R_{\psi}(x_F)$ for $J/\psi$ and $\psi(2S)$ production with a 800-GeV/c proton beam from the E771 experiment [91]. The ratios of total cross sections and individual $R_{\psi}^{\text{J}\psi}(x_F)$ and $R_{\psi}^{\text{GG}}(x_F)$ contributions are denoted as solid black, dashed blue, and dotted red lines, respectively.
FIG. 14. Differential cross sections for $J/\psi$ production with a 300-GeV/$c$ proton beam from the E705 experiment [83]. The data are compared to the NRQCD fit results of LDMEs for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively.
FIG. 15. Differential cross sections for $J/\psi$ production with a 200-GeV/c proton beam from the NA3 experiment [84]. The data are compared to the NRQCD fit results of LDMEs for the SMRS, GRV, xFitter, and JAM PDFs. The total cross sections and $q\bar{q}$, $GG$, and $qG$ contributions are denoted as solid black, dashed blue, dotted red, and dot-dashed green lines, respectively.
FIG. 16. Integrated charmonium cross sections in $pN$ and $\pi^- N$ collisions. The data for $J/\psi$ and $\psi(2S)$ production are compared to the fit made using the GRV pion PDFs. The total cross section and its $q\bar{q}$ and $GG$ contributions are denoted as solid black, dashed blue and dotted red lines, respectively. The yellow bands represent the cross section uncertainties associated with the scale and charm quark mass systematic variations.
FIG. 17. Integrated charmonium cross sections in $pN$ and $\pi^- N$ collisions. The data for $J/\psi$ and $\psi(2S)$ production are compared to the fit made using the JAM pion PDFs. The total cross section and its $q\bar{q}$ and $GG$ contributions are denoted as solid black, dashed blue and dotted red lines, respectively. The uncertainty bands associated with JAM PDFs are also shown. The yellow bands represent the cross section uncertainties associated with the scale and charm quark mass systematic variations.
FIG. 18. Integrated charmonium cross sections in $pN$ and $\pi^- N$ collisions. The data for $J/\psi$ and $\psi(2S)$ production are compared to the fit made using the xFitter pion PDFs. The total cross section and its $q\bar{q}$ and $GG$ contributions are denoted as solid black, dashed blue and dotted red lines, respectively. The uncertainty bands associated with xFitter PDFs are also shown. The yellow bands represent the cross section uncertainties associated with the scale and charm quark mass systematic variations.
FIG. 19. The NRQCD results with variation of charm quark mass \( m_c \) and renormalization scale \( \mu_R \), compared with the \( d\sigma/dx_F \) data of \( J/\psi \) production off the beryllium target with a 515-GeV/\( c \) beam from the E672/E706 experiment [82]. The pion PDFs used for the calculation is GRV. The total cross sections and \( q\bar{q}, GG, \) and \( qG \) contributions are denoted as solid black, dashed blue, dotted red and dot-dashed green lines, respectively. The charm quark mass \( m_c \), factorization scale \( \mu_F \), and renormalization scale \( \mu_R \) used for the NRQCD calculation as well as the fit \( \chi^2/\text{ndf} \) are displayed in each plot.

FIG. 20. Same as Fig. 19 but with the input of JAM pion PDFs.

FIG. 21. Same as Fig. 19 but with the input of xFitter pion PDFs.
### TABLE V. The reduced $\chi^2/\text{ndf}$ of values for the whole data sets and the $\chi^2$ divided by the number of data point (ndf) for the pion-induced and proton-induced datasets with the systematic variation of charm quark mass $m_c$ of 1.4, 1.5, and 1.6 GeV/$c^2$, and $\mu = \mu_R = \mu_F$ at 1.0, 2.0, and 4.0 $m_c$ in NRQCD calculations and the corresponding input or best-fit LDMEs for SMRS pion PDFs. All LDMEs are in units of GeV$^3$.

| $m_c$ (GeV/$c^2$) | 1 | 1.4 | 1.5 | 1.6 |
|-------------------|---|-----|-----|-----|
| $\mu/m_c$        |   |     |     |     |
