(Received 24 September 2008; published 19 March 2009)

Experimental realization and quantitative investigation of common-noise-induced synchronization of limit-cycle oscillations subject to random telegraph signals are performed using an electronic oscillator circuit. Based on our previous formulation [K. Nagai \textit{et al.}, Phys. Rev. E \textbf{71}, 036217 (2005)], dynamics of the circuit is described as random-phase mappings between two limit cycles. Lyapunov exponents characterizing the degree of synchronization are estimated from experimentally determined phase maps and compared with linear damping rates of phase differences measured directly. Noisy on-off intermittency of the phase difference as predicted by the theory is also confirmed experimentally.

I. INTRODUCTION

Synchronization of nonlinear dynamical elements is observed in many natural systems \cite{1,2}. For instance, in our body, heart cells synchronize with each other to generate heartbeats, and suprachiasmatic neurons synchronize with the 24 h daily cycle to generate circadian rhythms \cite{3,4}. Many experimental investigations of synchronization have been carried out, e.g., using coupled chemical reactors \cite{5–7}. Synchronization typically occurs due to mutual coupling or through entrainment to common periodic signals. Generally, external noises independently applied to the elements have negative effects on synchronization; the elements cannot synchronize under independent noise sources that are too extreme.

In contrast, common or correlated external noises can synchronize uncoupled dynamical elements. Using neurons of rat neocortical slices, Mainen and Sejnowski \cite{8} showed that reliability of spike generation improves when a neuron receives a fluctuating input current compared with the case of a constant input current. This phenomenon can be considered as synchronization of uncoupled identical dynamical elements induced by common fluctuating inputs. The synchronization effect of common fluctuating forcing, known in ecology as the Moran effect, describes the synchronized population dynamics of organisms due to correlated environmental fluctuations \cite{9}.

More explicitly, Pikovsky \cite{10} and Jensen \cite{11} theoretically investigated synchronization of limit-cycle oscillators induced by nonperiodic external signals. Synchronization of uncoupled chaotic oscillators due to common noisy driving was numerically studied by Maritan and Banavar \cite{12} and experimentally realized by Sánchez \textit{et al.} \cite{13} using an electronic circuit. Synchronization (or consistency) of chaotic lasers due to common fluctuating signals has also been reported \cite{14}.

For limit-cycle oscillators, general quantitative formulations of common-noise-induced synchronization can be developed using the phase-reduction method \cite{1}. Teramae and Tanaka \cite{15} proved that the synchronized state of uncoupled limit-cycle oscillators subject to a common weak Gaussian noise is always statistically stabilized, and their theory has been further generalized to provide global stability of phase-coherent states induced by correlated noises \cite{16}. The cases where limit-cycle oscillators are stimulated by a common telegraph noise \cite{17} or by a common impulsive noise \cite{18} have also been investigated theoretically using random phase-map descriptions. Recently, synchronization due to common random impulses has been studied experimentally with an electronic circuit, and some of the theoretical predictions have been quantitatively verified \cite{19}.

In this paper, we experimentally investigate common-noise-induced synchronization using an electronic circuit undergoing periodic oscillations. As the random signal, we use a random telegraph noise, which is the simplest example of colored non-Gaussian noises. It can easily be generated in experiments and facilitates analytical treatments. In this case, we have two limit cycles corresponding to two values of the driving signal, in contrast to the previous experiment using random impulses where the system possessed only a single limit-cycle orbit \cite{19}. When the switching interval of the driving signal is sufficiently long, the circuit state is mostly on either of the limit cycles at the moments of switching, so that its dynamics can be described in terms of phase mappings between the two limit cycles. We experimentally determine the phase maps of the electronic circuit and estimate the Lyapunov exponents characterizing the degree of synchronization from the phase maps based on our previous theory. The Lyapunov exponents are then quantitatively compared with the damping rates of small phase differences measured directly. We also confirm that noisy on-off intermittency of the phase difference, which is typically expected for random-mapping systems \cite{17,20–23}, actually occurs in our electronic circuit.

II. EXPERIMENTS

A. Setup

The experiments were performed using an electronic circuit shown schematically in Fig. 1(a), where an LM741 was used as the operational amplifier (op-amp) and the circuit parameters were set as follows: \( R_1=100\pm5\ \text{k}\Omega \), \( R_2=81\pm4.5\ \text{k}\Omega \), \( R_3=470\pm23.5\ \text{k}\Omega \), \( R_4=100\pm5\ \text{\Omega} \),
$C_1=100\pm5$ nF, and $C_2=10\pm1$ $\mu$F. Voltages of positive and negative power supplies to the op-amp were fixed at $\pm3.0$ V (0 V indicates the ground voltage) using a dc power source (PMM18-2.5DU, Kikusui Electronics Co.). Note that we use the op-amp under positive feedback conditions to generate oscillations, so that the golden rule of an op-amp ($V_+=V_-$) does not hold in our experiments.

The source voltage of the metal-oxide semiconductor field-effect transistor (MOSFET) (2SK2201, Toshiba Co.) was fixed at $-4.0$ V with another dc power source (E3630A, Hewlett Packard). The gate voltage $V_g(t)$ was controlled by the external signal. Voltage traces $V_+(t)$ and $V_-(t)$ were measured from the circuit as shown in Fig. 1(a). Control of $V_g(t)$ and measurements of $V_+(t)$ and $V_-(t)$ were performed with an analog-digital (AD)/digital-analog (DA) converter AI0-163202F-PE (Contec Co.). When $V_+(t)$ was fixed at a constant value between $-6.0$ and $-2.45$ V, the circuit exhibited limit-cycle oscillations. Figure 1(b) shows a limit-cycle orbit on $(V_+, V_-)$ plane at $V_g(t)=-6.0$ V, and Fig. 1(c) displays the corresponding time series of $V_+(t)$ and $V_-(t)$.

We repeatedly switched the gate voltage $V_g(t)$ between two values $V_{g1}$ and $V_{g2}$ to simulate a random telegraph signal. The switching events obeyed a computer-generated Poisson process, namely, the switching interval $D$ was an exponentially distributed random variable with mean interval $\tau =0.2$ s. We generated $D$ by the formula $D=-1/\tau \log(1-u)$, with $u$ being computer-generated pseudorandom numbers in $[0,1]$. The typical relaxation time of the circuit to converge to either of the limit cycles was shorter than 0.01 s. By applying the same time sequence of $V_g(t)$ to the circuit repeatedly, we performed consecutive measurements of the time series of $V_+(t)$, and then repeated this procedure with different realizations of the random telegraph signals. In the experiment, $V_{g1}$ was fixed to $-6.0$ V and $V_{g2}$ was varied between $-6.0$ and $-2.45$ V.

We defined a phase $\phi(t)$ of the circuit state from the time series of $V_+(t)$ as follows. The origin of the phase ($\phi=0$) was taken as the moment when $V_+(t)$ changed its sign from negative to positive. Each time $V_+(t)$ crossed 0 V from negative to positive, the phase was reset to 0. Between successive zero-crossing events, the phase was increased with a constant frequency from 0 to 1. Note that the frequency of the oscillator was not constant but changed from cycle to cycle due to random switching of the driving signal. From the two consecutive time series of $V_+(t)$, we obtained time series of the absolute phase differences $|\Delta \phi(t)|$ between two experimental trials (restricted to $[0,1]$) using the periodicity of the oscillator under the same time sequence of $V_g(t)$.

**B. Results**

Figure 2(a) shows the time evolution of the absolute phase difference $|\Delta \phi(t)|$ between two experimental trials under a constant input, $V_g(t)=V_{g1}=-6.0$ V, which increased linearly with time $t$. Even after fine tuning, we observe that the average period of oscillations differed slightly across experimental trials ($\pm0.1\%$).

Figures 2(b) and 2(c) show the time series of $\Delta \phi(t)$ observed under the common telegraph noise, where $V_g(t)$ was switched between two values ($V_{g1}=-6.0$ V and $V_{g2}=-2.5$ V). Large changes in $|\Delta \phi(t)|$ were observed only in short time windows after the switching events of $V_g(t)$ as shown in Fig. 2(b). The two experimental trials driven with
the same input signal became mostly synchronized, but occasionally there were interruptions by short desynchronization events as shown in Fig. 2(c).

To characterize this characteristic intermittent behavior of the phase difference, we measured the distribution of laminar intervals during which \(|\Delta \phi(t)| \leq 0.01\). As shown in Fig. 2(d), the stationary distribution of laminar intervals appeared to follow a power law, whose exponent was approximately \(-1.5\). We also measured the stationary distribution of the absolute phase difference \(|\Delta \phi(t)|\), which also exhibited a power-law tail with an exponent of roughly \(-1\) [Fig. 2(e)]. Though the phase difference \(|\Delta \phi(t)|\) shown in the figure is restricted to the range \([0,1]\), the phase difference occasionally exhibited jumps of magnitude 1 due to phase slippage of one period [e.g., near \(t=1200\) and \(t=1600\) in Fig. 2(c)] [24].

Thus, when the gate voltage \(V_g(t)\) was switched between two values randomly, different experimental trials tended to be synchronized even under the effect of slight differences in average periods and experimental noise. As we explain later, the characteristic behavior of the phase difference \(|\Delta \phi(t)|\) was due to noisy off-on intermittency [17,20–23].

III. ANALYSIS

A. Theory

Here we briefly summarize our previous theory on the synchronization of uncoupled oscillators driven by a common random telegraph signal [17]. Corresponding to the two different values of the input signal \(V_g(t)\), the circuit exhibits two different limit cycles, LC1 for \(V_g(t) = V_{g1}\) and LC2 for \(V_g(t) = V_{g2}\). When \(V_g(t) = V_{g1}\), we can define a phase \(0 \leq \theta(V_+ , V_-) < 1\) for LC1 and also in the \((V_+ , V_-)\) plane, which increases with a constant frequency \(1/T_1\), with \(T_1\) as the period of LC1 [1,3]. Similarly, when \(V_g(t) = V_{g2}\), another phase \(0 \leq \theta(V_+ , V_-) < 1\) can be defined in the \((V_+ , V_-)\) plane that increases with a constant frequency \(1/T_2\), where \(T_2\) is the period of LC2. The origins of \(\theta_1\) and \(\theta_2\) are taken as the points where \(V_g(t)\) crosses 0 V from negative to positive on LC1 or LC2. Combining these, we introduce a new phase \(\theta(V_+ , V_- , V_g)\) of the circuit state as

\[
\theta(V_+ , V_- , V_g) = \begin{cases} 
\theta_1(V_+ , V_-) & \text{when } V_g = V_{g1} \\
\theta_2(V_+ , V_-) & \text{when } V_g = V_{g2}
\end{cases}
\]  

Note that this \(\theta\) is different from the phase \(\phi\) that we defined in Sec. II by linearly interpolating successive zero-crossing events. \(\theta\) jumps discontinuously at the moments when \(V_g(t)\) switches, because \(\theta_1\) and \(\theta_2\) increase with strictly constant frequencies. In contrast, \(\phi\) is continuous even when \(V_g(t)\) is fluctuating except the zero-crossing events of \(V_g(t)\), but its frequency differs from cycle to cycle. When \(V_g(t)\) is kept constant for longer than one period of oscillation and than the relaxation time of the circuit to the limit cycle, \(\phi\) coincides with \(\theta\). This difference in the definition of the phase variables yields only small bounded discrepancies in measuring the phase differences between two time series.

We assume that the average switching time of the input signal, \(\tau\), is sufficiently longer than the relaxation time of the orbit to LC1 or LC2 at fixed \(V_g(t)\). In our experiments, we took \(\tau=0.2\) s and the relaxation time was typically shorter than 0.01 s, so that this condition was satisfied. The orbit of the circuit is then almost always on one of the limit cycles when \(V_g(t)\) is switched between two values. Therefore, we can describe the dynamics of the circuit under randomly switched \(V_g(t)\) as alternating phase mappings between \(\theta_1\) and \(\theta_2\) as shown in Fig. 3. We denote the mapping from \(\theta_1\) to \(\theta_2\) that takes place when \(V_g(t)\) switches from \(V_{g1}\) to \(V_{g2}\) as \(\theta_2 = \theta_1 + \Delta \theta_1\), and the mapping from \(\theta_2\) to \(\theta_1\) when \(V_g(t)\) switches from \(V_{g2}\) to \(V_{g1}\) as \(\theta_1 = \theta_2 + \Delta \theta_2\) [17].

Let us denote the phase on LC1 just before \(V_g(t)\) switches from \(V_{g1}\) to \(V_{g2}\) for the \(n\)th time as \(\theta_1^n\), and the phase on LC2 just before \(V_g(t)\) switches from \(V_{g2}\) to \(V_{g1}\) for the \(n\)th time as \(\theta_2^n\). Then the phase dynamics of the orbit can be described as [assuming \(V_g(t=0)=V_{g1}\)]

\[
\theta_1^{n+1} = f_{12}(\theta_2^n) + s_1^{n+1}, \quad \theta_2^{n+1} = f_{21}(\theta_1^n) + s_2^n,
\]

where \(s_1^n\) and \(s_2^n\) are exponentially distributed random switching intervals whose probability distributions are given by

\[
P_1(s_1^n) = \frac{T_1}{\tau} \exp\left(-\frac{s_1^n T_1}{\tau}\right), \quad P_2(s_2^n) = \frac{T_2}{\tau} \exp\left(-\frac{s_2^n T_2}{\tau}\right),
\]

respectively. Small deviations \(\Delta \theta_1^n\), \(\Delta \theta_2^n\) from \(\theta_1^n\), \(\theta_2^n\) obey linearized equations

\[
\Delta \theta_1^{n+1} = f_{12}'(\theta_2^n)\Delta \theta_2^n, \quad \Delta \theta_2^{n+1} = f_{21}'(\theta_1^n)\Delta \theta_1^n,
\]

where \(f'\) denotes the derivative function of \(f\). After the \(n\)th switching, the amplitude of the deviation \(\Delta \theta_1^n\) is given by

\[
|\Delta \theta_1^n| = \left| \prod_{i=1}^{n-1} f_{12}'(\theta_2^i) \right| |\Delta \theta_1^i|, \quad |\Delta \theta_2^n| = |\Delta \theta_2^n| = \exp(\lambda n)
\]

holds, where the Lyapunov exponent \(\lambda\) is given by
After setting $T_1$ and $T_2$ when than this condition was satisfied.

\[ f = \frac{n}{H_{11229}} g_2 \]

We experimentally determined the phase maps $\Phi_i^1$ and $\Phi_i^2$ just after $t_i^f$ and $t_i^r$ were obtained from $\Phi_i^1$ and $\Phi_i^2$ as

\[ \tilde{\Phi}_i^1 = \left( \Phi_i^{i+1} - \frac{d_{i+1}}{T_1} \right) \mod 1, \quad \tilde{\Phi}_i^2 = \left( \Phi_i^2 - \frac{d_i}{T_2} \right) \mod 1, \]

where the definitions were made modulo 1 to restrict the phases to $[0,1]$. Thus, we obtained 200 realizations of the phase mappings,

\[ \{ \Phi_i^1 \rightarrow \tilde{\Phi}_i^1 \mid i = 1, \ldots, 200 \}, \quad \{ \Phi_i^2 \rightarrow \tilde{\Phi}_i^2 \mid i = 1, \ldots, 200 \}. \]

We constructed the raw phase maps by piecewise linearly interpolating these data as

\[ \tilde{\Phi}_2 = f_{12}^{raw}(\Phi_2), \quad \tilde{\Phi}_1 = f_{21}^{raw}(\Phi_1), \]

which were still nonsmooth functions due to experimental fluctuations.

Generally, the phase map has a trivial diagonal component, namely, the identity-map component that exists even when $V_g = V_{g2}$, and additional nontrivial components reflecting the nonlinear transition dynamics between the limit cycles. We estimated the underlying smooth phase maps $f_{12}^{raw}$ and $f_{21}^{raw}$ by low-pass filtering using the 20 lowest Fourier modes as

\[ t_i^f = d_1, \quad t_i^r = d_i + \sum_{k=1}^{i-1} 2d_k, \quad i \geq 2, \quad (11) \]

and the subsequent $i$th switching time from $V_{g2}$ to $V_{g1}$ is given by

\[ t_i^r = \sum_{k=1}^{i} 2d_k, \quad i \geq 1. \]

Here, $d_i$ denotes the length of the $i$th constant interval of the input signal. To avoid undesirable synchronization with the probe signal, we gradually increased $d_i$ as $d_i = 0.5 + 0.001(i - 1)$ $(1 \leq i \leq 200)$.

Using this $V_g(t)$, we measured the phase $0 \leq \Phi_i^1 < 1$ of the circuit at $t_i^f$,

\[ \{(\Phi_i^1, t_i^f) \mid i = 1, \ldots, 200\}, \]

and the phase $0 \leq \Phi_i^2 < 1$ of the circuit at $t_i^r$,

\[ \{(\Phi_i^2, t_i^r) \mid i = 1, \ldots, 200\}. \]

These phases $\Phi_i^1$ and $\Phi_i^2$ can be identified with the phases $\theta_1$ and $\theta_2$ used in the theory via

\[ \theta_1(t = t_i^f) = \Phi_i^1, \quad \theta_2(t = t_i^r) = \Phi_i^2. \]

Note that the two types of the phases coincide here because the constant intervals $d_i$ of the probe signal are always longer than $T_1$, $T_2$, and the relaxation time of the circuit to LC1 or LC2.

At each switching event, the phase jumped from $\Phi_i^1$ to $\Phi_{i+1}^1$ ($V_{g1} \rightarrow V_{g2}$), or from $\Phi_i^2$ to $\Phi_{i+1}^2$ ($V_{g2} \rightarrow V_{g1}$). The destination phases $\tilde{\Phi}_i^1$ and $\tilde{\Phi}_i^2$ just after $t_i^f$ and $t_i^r$ were obtained from $\Phi_i^1$ and $\Phi_i^2$ as

\[ \tilde{\Phi}_i^1 = \left( \Phi_i^{i+1} - \frac{d_{i+1}}{T_1} \right) \mod 1, \quad \tilde{\Phi}_i^2 = \left( \Phi_i^2 - \frac{d_i}{T_2} \right) \mod 1, \]

holds for large $n,t$.

**B. Determination of phase maps**

We experimentally determined the phase maps $\theta_i = f_{12}(\theta_2)$ and $\theta_i = f_{12}(\theta_1)$ as follows. We first measured the period $T_1$ of LC1 under a constant input signal $V_g(t) = V_{g1}$. After setting $V_g(t)$ at $V_{g1}$ and relaxing the circuit for 0.5 s, intervals between successive zero-crossing events of $V_g(t)$ from negative to positive values were measured for 5 s. $T_1$ was determined by averaging these intervals. We then measured the period $T_2$ of LC2 at $V_g(t) = V_{g2}$ in a similar way.

When the measurement of $T_2$ was completed (this moment was defined as $t=0$), the following regular telegraph signal (shown schematically in Fig. 4) was applied as the probing input:

\[ V_g(t) = \begin{cases} V_{g1}, & t_i^f - 1 \leq t < t_i^f, \\ V_{g2}, & t_i^f \leq t < t_i^r, \end{cases} \]

for $i = 1, \ldots, 200$, where the $i$th switching time from $V_{g1}$ to $V_{g2}$ is given by

\[ \lambda = \lim_{n \to \infty} \frac{1}{n} \left( \sum_{i=1}^{n} |f_{12}(\theta_i)| \right) = \lambda_1 + \lambda_2. \]

Here, we approximate the average over the stationary distribution of the phase $\theta_i$ or $\theta_i'$ under the effect of telegraph noises by the average over the uniform distribution in each equation, because the phases $\theta_1$ and $\theta_2$ are almost uniformly distributed on LC1 and LC2 when $\tau$ is sufficiently larger than $T_1$ and $T_2$ [17]. In our experiments, we used $\tau = 0.2$, whereas the period of oscillations was about 0.05 s. Therefore, this condition was satisfied.

When $\lambda = \lambda_1 + \lambda_2 < 0$, phase synchronization induced by the random telegraph signal is expected. Note that the switching step $n$ is approximately related to the real time $t$ as $n = t/2\tau$, so that

\[ \frac{\Delta \theta(t)}{\Delta \theta(0)} = \exp \left( \frac{\lambda}{2\tau} \right) \]

FIG. 4. (Color online) The probe signal used to determine the phase maps. Before $t=0$, $T_1$ and $T_2$ were measured. After $t=0$, the phases were measured at $t_i^f$ and $t_i^r$ for $1 \leq i \leq 200$. 

\[ \Phi_i^1 = \Phi_{i+1}^1 - \frac{d_{i+1}}{T_1}, \quad \Phi_i^2 = \Phi_{i+1}^2 - \frac{d_i}{T_2}, \]

for $i = 1, \ldots, 200$, where the $i$th switching time from $V_{g1}$ to $V_{g2}$ is given by
where $c_{12}$ and $c_{21}$ are Fourier coefficients of the nontrivial components of $f_{12}^{\text{raw}}$ and $f_{21}^{\text{raw}}$, defined as

$$f_{12}^{\text{raw}}(\Phi_1) - \Phi_1 = \sum_{k=-\infty}^{\infty} c_{12}^k \exp(2\pi ik\theta_1),$$

and

$$f_{21}^{\text{raw}}(\Phi_2) - \Phi_2 = \sum_{k=-\infty}^{\infty} c_{21}^k \exp(2\pi ik\theta_2),$$

where $c_{12}^k$ and $c_{21}^k$ are Fourier coefficients of the nontrivial components of $f_{12}^{\text{raw}}$ and $f_{21}^{\text{raw}}$, defined as

$$(\hat{\Delta} \phi_1) \sim \exp(r_{\text{damp}} t),$$

where $r_{\text{damp}} < 0$ is the damping rate. As the average switching interval of $V_g(t)$ is $\tau$,

$$r_{\text{damp}} = \frac{\lambda}{2\tau},$$

will approximately hold for large $t$ and $n$ provided that the previous analysis based on the phase-mapping description is reasonable.

Figure 5(b) compares the Lyapunov exponent $\lambda$ with the damping rate $r_{\text{damp}}$ obtained for different values of $V_g$ with fixed $V_i$. The damping rate $r_{\text{damp}}$ was directly measured from $|\Delta \phi(t)|$ as

$$r_{\text{damp}} = \frac{1}{M^{-1}\sum_{i=1}^{M} |\Delta T_i|} \ln \left| \frac{\Delta \phi_{\text{lower}}}{\Delta \phi_{\text{upper}}} \right|,$$

where $\Delta \phi_{\text{upper}} = 0.2$, $\Delta \phi_{\text{lower}} = 0.05$, $\Delta T_i$ is the time needed for $|\Delta \phi|$ to be damped from $\Delta \phi_{\text{upper}}$ to $\Delta \phi_{\text{lower}}$, and $M$ is the number of such shrinkage events in the time series of $|\Delta \phi(t)|$. We measured 20 time sequences of $V_g(t)$ for 120 s and calculated 19 time sequences of the phase difference $\Delta \phi(t)$ between two consecutive time sequences of $V_g(t)$ to obtain $r_{\text{damp}}$. As shown in Fig. 5(c), pairs of $(\lambda, r_{\text{damp}})$ esti-

**D. Noisy on-off intermittency**

We have focused so far on the average behavior of the phase difference. The phase difference $|\Delta \phi(t)|$ decreases on average when $\lambda = \lambda_1 + \lambda_2 < 0$. However, as can be seen from Eq. (5), small phase differences $\Delta \theta_1$ and $\Delta \theta_2$ are driven multiplicatively by the random application of two phase maps. This is a typical situation where noisy on-off (or modulatory) intermittency is expected over long time scales [17,20–23]. Due to small noises or heterogeneity inherent in the system, individual time sequence of $|\Delta \phi(t)|$ can occa-
sionally grow due to random multiplication even if $\lambda = \lambda_1 + \lambda_2 < 0$, resulting in repetitive transient bursting. As already shown in Figs. 2(d) and 2(e), this is the case for our electronic circuit. The power-law distribution of the laminar interval with the exponent of $-1.5$ as shown in Fig. 2(d), and the power-law distribution of the amplitude of the phase difference as shown in Fig. 2(e) are consistent with the theoretical predictions on noisy on-off intermittency [20–23].

IV. CONCLUSIONS

We investigated synchronization between different experimental trials induced by common telegraph noises using an electronic circuit undergoing limit-cycle oscillations. The dynamics of the circuit could be described in terms of random phase mappings. We experimentally determined the phase maps and quantitatively verified that the Lyapunov exponents determined from the phase maps agreed with the damping rates measured directly from the time series of small phase differences. We also confirmed that noisy on-off intermittency of the phase difference actually occurs.

The mechanism leading to synchronization that we demonstrated using an electronic circuit in this paper is general and is expected to be observed in various systems undergoing limit-cycle oscillations.

ACKNOWLEDGMENTS

We thank Kensuke Arai (Kyoto University, Japan) for helpful discussions and advice. This work was supported in part by a Grant-in-Aid from JSPS to K.N. (Grant No. 18–3189 and the 21st Century COE (Center for Diversity and Universality in Physics) from the Ministry of Education, Culture, Sports, Science and Technology of Japan.
