The recent emergence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has led society to live with a serious public health problem. In this sense, repositioning of antiretrovirals has captured the attention of the scientific community. Tenofovir disoproxil fumarate (TDF) is an antiretroviral compound that is used to treat acquired immune deficiency syndrome (AIDS) and hepatitis B. In this short report, we present a scale-up investigation of TDF by \textit{in situ} infrared spectroscopy monitoring and a forced degradation study to describe a new degradation product. Finally, we have evaluated TDF \textit{in vitro} for SARS-CoV-2 for the first time foreseeing the using of this medicine in pre-clinical and clinical investigations for the COVID-19 (coronavirus disease 2019) treatment.

\textbf{Keywords:} tenofovir disoproxil fumarate, scale-up studies, putative metabolites, SARS-CoV-2, COVID-19, infrared spectroscopy, electrospray ionization mass spectrometry

\textbf{Introduction}

Revealed in December 2019 in Wuhan, Hubei Province, China, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is associated with a continuous outbreak of atypical pneumonia, designated COVID-19 (coronavirus disease 2019).\textsuperscript{1} It is a rapidly spreading virus, and providing timely treatment of patients with this disease is essential.\textsuperscript{1} Developing new drugs from the beginning represents an impractical initiative as an immediate solution. In the midst of anxiety, repositioning drugs is a promising strategy.\textsuperscript{2}

Tenofovir disoproxil fumarate (TDF) is an antiretroviral compound that is applied to treat patients with acquired immune deficiency syndrome (AIDS) and hepatitis B. TDF, a pro-drug of tenofovir, works as a nucleoside analogue reverse transcriptase inhibitor and was designed to improve absorption and cell permeability.\textsuperscript{3} The world press have been reported on advances with remdesivir, a medication of the same class as TDF, in accelerating the recovery of COVID-19 patients, by virus RNA polymerase inhibition.\textsuperscript{4} Although we do not have complete and conclusive clinical data that suggest a mechanism

of action for the use of tenofovir and its analogs to treat patients with COVID-19, the attempt to reposition is a valid strategy that can reduce the time that is necessary to develop a treatment or an adjuvant.

This initiative has stimulated several research groups to work on scale-up and optimizations of the protocols. We are engaged on this, and also decided to investigate TDF as one of the active pharmaceutical ingredients (APIs) against COVID-19 infection. Thus, we report our results on TDF preparation from adenine in a pilot plant-scale through Fourier transform infrared spectroscopy (FTIR) in-line monitoring. To reinforce the safe use of TDF, we have conducted a forced degradation study. Finally, we have evaluated the pure samples in vitro to inhibit SARS-CoV-2 assay looking to support the repositioning of this API.

**Experimental**

The synthetic strategy was based on a previously published bench work, and all the experimental details and modifications are described in the Supplementary Information (SI) section. Scale-up studies were performed in a Büchiglasuster MiniPilot R15 multipurpose pilot reactor system equipped with a Huber Unistat 510 Dynamic temperature control system. The reactions were monitored in situ by infrared spectroscopy in the frequency range of 2500-650 cm⁻¹; a ReactIR 15® Mettler Toledo spectrometer connected with an attenuated total reflectance (ATR) fiber probe was employed. Racemic 4 was used in the scale-up studies.

The forced degradation study was carried out under more extreme conditions. The stress conditions employed in this study were modified from a previous work and standardized, and they are presented in the SI section. The liquid chromatography-electrospray ionization-mass spectrometry (LC-ESI-MS) protocol is also depicted in the SI section.

To test whether TDF or tenofovir affected SARS-CoV-2 in vitro infection, sub-confluent monolayers of Vero CCL-81 cells (American Type Culture Collection, Manassas, VA, USA) were treated with 3 μM TDF or left untreated for 24 h, which was followed by incubation of the monolayers with SARS-CoV-2 stocks (multiplicity of infection (MOI) 1) on a rocker at 4 °C for 2 h, for virus adsorption. The monolayers were washed with ice-cold phosphate buffered saline (PBS) and incubated with 0.5 mL of Dulbecco’s modified Eagle medium (DMEM) (Life Technologies, Carlsbad, USA) without fetal bovine serum (FBS). The latter incubation was conducted at 37 °C and in 5% CO₂, in the absence or presence of 3 μM TDF. Supernatants from triplicate monolayers were collected 48 h after infection and had their total RNA extracted with Trizol®, to quantify the viral genome load by one-step TaqMan real-time quantitative reverse transcriptase-polymerase chain reaction (1-step RT-qPCR). The SARS-CoV-2 genome was detected by using primer-probe set for 2019-nCoV_N1 gene, according to the USA-CDC (Centers for Disease Control and Prevention) protocol. 7 1-Step RT-qPCR for RNaseP, as housekeeping gene, was done for all the samples. 8 All the qPCR assays were carried out on the Step-One Plus real-time PCR thermocycler (Applied Biosystems, Foster City, CA, USA). Briefly, after Trizol® extraction, 100 ng of each RNA sample were used in the one-step RT-qPCR, with N1 primers and TaqPath 1-Step RT-qPCR Master Mix (Applied Biosystems, Foster City, CA, USA). One-step RT-qPCR was accomplished in a final volume of 20 μL by employing 100 ng of RNA, 20 μM forward and reverse N1 primers, 5 μM N1 probe, and 5 μL of TaqPath 1-Step RT-qPCR Master Mix (Applied Biosystems, Foster City, CA, USA). The following parameters were used: 25 °C for 2 min, 50 °C for 15 min for RT incubation, 95 °C for 2 min for enzyme activation, followed by 45 cycles of 94 °C for 5 s and 60 °C for 30 s, with final soaking at 10 °C. Variation in the cycle thresholds (ΔΔCT) of qPCR amplification of the virus genome was used to analyze virus yield in the tests.

Cytotoxicity and cell viability after treatment with tenofovir or TDF was determined by using the alamarBlue Cell Viability reagent (Thermo Scientific, Waltham, USA); the manufacturer’s instructions were followed. Briefly, monolayers of Vero CCL-81 cells in a 96-well plate were left untreated or were treated (in triplicate) with tenofovir or TDF at 3, 10, 30, 90, or 270 mM for 24 h. After this time, the cells were washed with PBS, and then they were re-incubated with DMEM without FBS and with the respective compound (tenofovir or TDF) concentration (3, 10, 30, 90, or 270 mM) for 48 h to simulate infection conditions. The alamarBlue reagent was added at 10% of the culture volume, and the cells were further incubated at 37 °C for 4 h. Fluorescence was measured on a SpectraMax (Molecular Devices) microplate reader; the excitation and the emission wavelength was 530 and 590 nm, respectively. The mean of the cell control (untreated) was set as 100%, and the cell viability of each treatment condition was calculated relative to this value.

The statistical data are shown as mean ± standard error of the mean (SEM) of experiments done in triplicate and significance was analyzed by one-way analysis of variance (ANOVA) with Bonferroni’s corrections. The P values are labeled as: ***P < 0.01; ****P < 0.001. Differences were considered statistically significant at P < 0.05. Data were plotted and analyzed using GraphPad Prism 5.0 software.
Results and Discussion

In 2010, Ripin and co-workers\textsuperscript{3,5} reported an important optimization in the TDF manufacture process. We chose this approach for our scale-up studies (up to 1 kg of the starting materials) of the TDF based on the FTIR-ATR in-line monitoring strategy\textsuperscript{10-12} that supported some modifications to the process on a pilot scale (Scheme 1). For example, by monitoring the consumption of substrate 3 (bands at 1805 and 1048 cm\textsuperscript{-1}) and the formation of 4 (bands at 1592 and 1297 cm\textsuperscript{-1}), we found that substitution of NaOH for K\textsubscript{2}CO\textsubscript{3} significantly accelerated the reaction between adenine and propylene carbonate in the first step of the route, to give the desired alcohol 4 in higher yield. Moreover, in the second reaction step, application of chemical and glassware drying techniques allowed us to use a reduced amount of the base, which afforded phosphonate diester 6 with improved yield. Furthermore, monitoring the bands at 1254 and 1685 cm\textsuperscript{-1} effectively helped to control the hydrolysis of 6 throughout step 3 of the process, which was completed within a shorter time to afford tenofovir 7 in 82% yield. In contrast, intrinsic characteristics of the last step of the process (i.e., the need for low concentration) made reliable FTIR-ATR in-line readings difficult, so we monitored the reactions that led to 1 from 7 by offline high-performance liquid chromatography (HPLC).

Forced degradation assays showed two known degradation products, as represented by the total ion chromatogram of TDF oxidation in peroxide condition (Figure S20, SI section). Tenofovir (m/z 288) also emerged as degradation product (DP) from TDF, and it was more evident in acidic and alkaline hydrolysis conditions, as already described.\textsuperscript{13} The third known DP was identified as tenofovir monosoproxil, also considered an impurity by the International Pharmacopoeia of the World Health Organization (2019).\textsuperscript{14} In addition, the most intense signal in the mass spectrum of the known DP with retention time of 23.7 min arose at m/z 536 (Figure S21d, SI section). The molecular mass of this DP corresponded to an increase of 16 Da in the TDF molecular mass, suggesting that an oxygen atom was introduced into the TDF chemical structure. A detailed analysis of gas-phase chemistry during ESI-MS/MS analysis has been accomplished to suggest the DP structures and to define safety protocols.\textsuperscript{15} In this way, a detailed analysis of TDF ESI-MS/MS (Figures S22 and S24, SI section) revealed the presence of some initial fragments with larger mass that corresponded to simple neutral eliminations. The key fragmentation pathway started with the ion at m/z 270: an internal rearrangement with the loss of the two side chains and the reaction of only one oxygen atom occurred (Figure S24, SI section). The next step was PO\textsubscript{2} elimination by anchimeric assistance, which was followed by H\textsubscript{2}CO elimination. The oxidative products showed the same fragmentation pathway with 16 more mass units, which suggested oxidation at the amino purine moiety (Figure S24, SI section). This DP has never been reported and was only observed for the oxidation in peroxide condition, which reinforces the importance of scaling up the oxidative reaction for complete characterization of the molecule.

As a preliminary analysis to investigate TDF as a possible candidate for drug repositioning against

\end{center}

\textbf{Scheme 1.} Synthetic route that was used to prepare 1 on a pilot scale.
SARS-CoV-2 infection, we tested how treatment with this drug affected viral replication in cell culture. The qRT-PCR results showed that treatment with TDF between 3 and 90 μM reduced the amount of released viral genome by approximately 15-fold (Figure 1a), which indicated that viral particle production declined significantly. In contrast, treatment with tenofovir in the same concentration range did not inhibit viral genome production (Figure 1a). Importantly, none of the drugs showed detectable cytotoxicity at these concentrations and incubation conditions (Figure 1b). Consistent with our results, TDF is much more active against human immunodeficiency virus (HIV) replication in MT-2 T-cells and peripheral blood mononuclear cells than tenofovir because TDF presents faster intracellular uptake and efficient accumulation (> 1000-fold higher) in the active form tenofovir diphosphate. Tenofovir and TDF metabolites inhibit HIV replication by acting as DNA chain terminators due to their capacity to bind the viral reverse transcriptase and to compete with the natural substrate deoxyadenosine 5'-triphosphate during viral complementary DNA synthesis. Interestingly, a recent molecular docking study indicated that tenofovir tightly binds to SARS-CoV-2 RNA-dependent RNA polymerase (RdRp), suggesting that this drug may also potentially inhibit the activity of this enzyme. Additionally, we have performed a docking study with the recently published cryogenic electron microscopy (cryo-EM) structure of SARS-CoV-2 RdRp (PDB id = 7BV2, 2.50 Å) that corroborates the binding of tenofovir to the same region occupied by remdesivir (see SI section). Although the mechanism underlying the TDF-mediated SARS-CoV-2 inhibition shown here remains to be unveiled, these results are encouraging and support additional research into the use of TDF in the treatment of patients with COVID-19.

Conclusions

In conclusion, scale-up studies on TDF based on FTIR-ATR in-line monitoring strategy allowed us to propose modifications to previous protocols and to control of the process, so now we are able to transfer the methodology to pharmaceutical companies to produce this API in our country. Stability studies showed a new degradation product which could be useful for the API quality control. Finally, the biological assay indicated that repositioning TDF to treat patients with COVID-19 is promising, and we hope it can stimulate further pre-clinical and clinical trials.
