ABSTRACT
We present an analysis of archival Spitzer InfraRed Spectrograph (IRS) observations of the recurrent nova RS Ophiuchi obtained on several occasions, beginning about 7 months after the outburst in 2006. These data show atomic emission lines, absorption bands due to photospheric SiO, and the well known silicate dust features at 9.7 μm and 18 μm. The dust emission, arising in the wind of the secondary star, is fitted by DUSTY models for mass-loss rates in the range 1.0 – 1.7 × 10^{-7} M⊙ yr^{-1}. The silicate features are similar to those seen in circumstellar environments of isolated late-type stars and some dusty symbiotic binaries, although the longer wavelength feature peaks at 17 μm, instead of the usual 18 μm, indicating peculiar grain properties. The dust features are variable, appearing stronger in 2006-2007 during outburst than in 2008-2009 when the system was in the quiescent state. This variability is attributed to changes in the ultraviolet output and the reformation of the accretion disk, although a decline in the mass-loss rate of the red giant secondary star could also play a role. Further observations, in the aftermath of the 2021 eruption, could provide a definitive conclusion.

Key words: biaries: symbiotic – circumstellar matter – stars: individual: RS Ophiuchi – novae: cataclysmic variables – infrared: stars

1 INTRODUCTION
RS Ophiuchi is a recurrent nova (RN) which has shown at least nine outbursts since 1898; the most recent occurred in 2021 (Cheung, Ciprini & Johnson 2021). The system consists of a massive white dwarf (1.2 – 1.4 M⊙; Mikolajewska & Shara 2017) and a red giant (∼0.8 M⊙) in a 433.6±0.4 day period binary (Brandi et al. 2009; Fekel et al. 2004). As in classical novae, the RN outbursts are caused by a thermonuclear runaway on the surface of the white dwarf in material accreted from the secondary star (Starrfield 2008).

RS Oph belongs to a subcategory of RNe that are similar to symbiotic systems, having a relatively long orbital period and a red giant secondary (Anupama 2008). In these systems, the nova ejecta shock the red giant wind (Bode & Kahn 1983), and the progress of the eruption in the X-ray and radio is similar to that of supernovae type-II, in which the outburst ejecta shock the material lost by the progenitor (for a discussion see Page et al. 2022).

Pavlenko et al. (2008) modelled a 2006 August spectrum of RS Oph in the 1.4 – 2.5 μm range and determined for the secondary T_{eff} = 4100±100 K, log g = 0.0±0.5 (spectral class M0-2 III; see also Rushton et al. 2010; Evans et al. 1983; Scott et al. 1994; Anupama & Mikolajewska 1999). [Fe/H] = 0.0 ± 0.5, [C/H] = −0.8 ± 0.2 and [N/H] = +0.6 ± 0.3. A red giant with these parameters typically has mass-loss 10^{-8} M⊙ yr^{-1} (Kudritzki & Reimers 1978), although symbiotics may lose mass more rapidly than isolated stars (Kenyon 1988). In the dusty (D-type) symbiotics, the mass-loss is accompanied by dust formation (Webster & Allen 1973).

The Roche lobe radius of the red giant in RS Oph
is $R_{\text{Roche}} = 120 - 150 R_\odot$ (with the binary parameters in Fekel et al. 2000, distance of 1.6 kpc from Snijders 1986 and white dwarf mass 1.35 $M_\odot$; Hachisu & Kato 2000), or about 3 times larger than the radius of an early M-type giant (van Belle et al. 1999). This suggests that the white dwarf captures some of the secondary wind, although it is unclear if this is able to supply all of the material involved in the outburst. Schaefer (2009) argues for mass transfer via Roche Lobe overflow. If this is the case, then the companion is more luminous ($\sim 5 \times 10^4 L_\odot$ for radius $R_\star = R_{\text{Roche}}$) than a typical early M-type giant ($\sim 600 L_\odot$ for $R_\star = 50 R_\odot$; van Belle et al. 1999), indicating a larger distance ($> 3$ kpc) than the widely accepted 1.6 kpc (Snijders 1986). A larger distance is implied by the Gaia (early Data Release 3) parallax measurement (2.4$^{+0.3}_{-0.2}$ kpc; Bailer-Jones et al. 2021), but this unreliable because of the effects of binary motion on the astrometry (see Montez et al. 2022).

Dust emission from the red giant wind was detected in quiescence by Geisel, Kleinmann & Low (1970) and by astrometry (see Montez et al. 2022). This unreliable because of the effects of binary motion on the astrometry (see Montez et al. 2022).

Figures 1. Spitzer spectrum of RS Oph on 2006 September 9 UT (209 days post-outburst) with various emission lines identified and the SIO fundamental. Silicate emission bands are also visible, with widths indicated by the dotted lines. The red dashed line is a power law ($F_\lambda \propto \lambda^{-n}$) fit to the continuum (defined in the range 5.6 – 7.5 $\mu$m and 30 – 37 $\mu$m) with spectral index $n = 3.01$.

2 OBSERVATIONS

Spitzer IRS observations of RS Oph were obtained on the dates shown in Table 1 Two spectra were obtained near the post outburst minimum, three spectra during the recovery, and three spectra in the quiescent state. The spectra were downloaded from the Combined Atlas of Sources with Spitzer IRS Spectra (CASSIS; Lebouteiller et al. 2011, 2013), which are reduced with a dedicated pipeline. The programs IDs are 270, 40060 (PI A. Evans), 30007 and 50011 (PI C. E. Woodward). The downloaded spectra were extracted using the optimal method, as recommended for point sources.

3 OVERVIEW OF THE SPECTRA

Figure 1 shows the Spitzer IRS data of RS Oph on 2006 September 9 UT. The emission lines are due to H$_1$, [Ne ii], [Ne iii], [Ne v], [Ne vi] and [O iv] and show a gradual weakening as the system approached quiescence following the 2006 outburst (see Evans et al. 2007 for details). The dotted line is a fit to the continuum using a power-law $F_\lambda \propto \lambda^{-n}$. The spectral index $n$ is given for all dates of observation in Table 1 (column 5).

The broad emission bands at 9.7 $\mu$m and 18 $\mu$m are the silicate dust (generally amorphous composition) features, which arise from the Si-O stretch (9.7 $\mu$m) and the O-Si-O bend (18 $\mu$m). They are present on all dates of observation, even on dates in 2007, when the dust excess is absent at shorter wavelengths (Rushton et al. 2010). The 2006 Sept to 2007 Apr spectra have been previously published by Evans et al. (2007a), who reported the appearance of the silicate features following the 2006 outburst. Spitzer data were also obtained on 2006 Apr 16, but the continuum is dominated by free-free emission from the nova ejecta at that time (Evans et al. 2007b).

The silicate features vary over the three years of observation, appearing stronger in the 2006 and 2007 data than in the 2008 and 2009 data (Figure 2). Table 1 (col-

$^\dagger$Φ = 0 corresponds to the time of maximum positive radial velocity of the red giant (Fekel et al. 2000).
$^\ddagger$Integrated flux in the $\lambda = 9.0 - 30 \mu m$ range.
$^\ast$Integrated flux in the $\lambda = 9.0 - 13.5 \mu m$ range.
umn 7) shows the flux emitted across the silicate bands (F,7.1–18 µm), which was obtained after the removal of the atomic lines and the subtraction of the continuum [the flux emitted across the 9.7 µm band (F,7.7 µm) is shown in column 8]. The 18 µm feature varies with the 9.7 µm band, although the 18 µm/9.7 µm ratio is variable, as can be seen in Figure 2. The 18 µm/9.7 µm ratio depends on the temperature, optical depth and relative age of the silicate material; specifically, the 18 µm feature is barely noticeable in freshly condensed dust (Nuth & Hecht 1990). The 18 µm/9.7 µm ratio in RS Oph is consistent with processed material, showing that the dust forms in the red giant wind and not in the nova ejecta (see also Evans et al. 2007a).

The silicate features are present in a range of astrophysical environments, although the 9.7 µm spectral profile depends on the composition and properties of the grains, appearing broader in young stellar objects and molecular clouds (Angeloni et al. 2007). The central wavelength of the 9.7 µm band is also environment dependent: the peak is at >9.8 µm in circumstellar and diffuse-medium environments, and 9.6 µm in molecular clouds (Pégourié & Papoulad 1983). In symbiotics stars, the peak occurs at longer wavelengths, >10.0 µm (Angeloni et al. 2007), as in RS Oph.

The band profiles and 18 µm/9.7 µm ratios show considerable variation among the symbiotic stars. RS Oph is most similar to R Aqr and CH Cyg, which have been likened to the silicate C group in the Speck et al. (2001) classification scheme for AGB stars. Like these symbiotics, in quiescence RS Oph lacks the highly ionised lines that are observed in the silicate A, B and D groups. This may be due to the presence in the inner binary of high density gas, preventing the formation of forbidden lines (Angeloni et al. 2007).

The full width at half maximum (FWHM) of the 9.7 µm silicate feature in RS Oph is given in column 11 of Table 1. To estimate the central wavelengths of the emission bands [λs(9.7), λs(18)], we followed the procedure of Angeloni et al. (2005), and fitted a gaussian curve to the upper portion of the dust features, which are reasonably well approximated by such a profile. The results of this procedure are shown in Table 1.

Figure 3 is a reproduction of Figure 4 in Angeloni et al. (2007), which shows the FWHM and central wavelength of the 9.7 µm band for a sample of symbiotic stars compared to other sources. The data in Table 1 are also included here. The FWHM of the silicate feature in RS Oph is narrower than that of the symbiotics stars in the sample, although it appears narrower in some 2007-2009 data than in the 2006 data. This can be seen in Figure 3, which shows the 9.7 µm feature in the 2006 October and 2007 April spectra (see also Evans et al. 2007a). Note that λs(9.7) is at a shorter wavelength in the 2007-2009 data, following this change.

The central wavelengths given in Table 1 are λC(9.7) = 10.44 ± 0.01 µm (2006), λC(9.7) = 10.36 ± 0.01 µm (2007-2008) and λC(18) = 16.65 ± 0.12 µm (2006-2009). These results are compared to those of other symbiotic stars in Figure 3. The dotted line is an empirical relation determined by Angeloni et al. from the stars in their sample, λC(18) = 1.39λC(9.7) + 3.73. It can be seen that the 9.7 µm feature in RS Oph is consistent with that of the other symbiotics in that the emission peak is at wavelengths >10 µm, although the 18 µm feature is significantly blueward of those of the stars in the sample.

We predict λs(18) = 18.13 ± 0.01 µm with λs(9.7) = 10.36 ± 0.01 and the relation. However, it is possible that a larger sample of symbiotic stars would include stars with peak emission at λs(18) < 17.5 µm. Furthermore, unlike the other stars in the sample, RS Oph is an eruptive variable and a better comparison could be made with the RN V745 Sco, which has a red giant secondary and a dust excess (Evans et al. 2014).

4 SIO FUNDAMENTAL BANDS

The RS Oph spectra show weak absorption in the 7–8 µm range, which could be due to the SiO fundamental (Δν = 1) bands. A close-up of this spectral region is shown by the black line in Figure 5. The coloured lines in the Figure are stellar model atmospheres, including SiO. The models are computed for T_{eff} = 3800 – 4200 K, and log g = 1.0. [C/H] = −0.8, [N/H] = −0.6 and microturbulent velocity of Vt = 3.0 km s^{-1} (Pavlenko et al. 2010). For the red giant in RS Oph, Pavlenko et al. (2010) determine T_{eff} = 3800 K from fits to optical spectra. The SiO absorption in this model (red line in Figure 5) is stronger than the observed absorption, but this may be due to dust veiling in RS Oph. The SiO bands are highly sensitive to T_{eff}, metallicity and Vt. We are unable to accurately determine these parameters from the Spitzer data alone. A detailed analysis of the SiO bands will be given elsewhere.

5 DUST PARAMETERS

5.1 The silicate profiles

The silicate features are fitted with extinction profiles to determine the shape, porosity and composition of the dust grains. A major problem with this type of analysis is that the interpretation of the spectra is restricted by the availability of laboratory data that provides appropriate optical constants. This shortcoming has been overcome for the interstellar medium by assuming an astronomical silicate, which is based on the emissivity of the Trapezium Nebula (Draine & Lee 1984). However, the properties of this silicate are uncertain and may not be representative of other environments.

Laboratory measurements to decipher the nature of the astronomical silicate are given in the HJPDOC database (Angeli et al. 1997) and Dorschner et al. (1995), who report constants for silicate glasses with a pyroxene (MgFe SiO) and olivine stoichiometry (Mg2Fe SiO) for x = 0.4 – 1.0 and y = 0.4 and 0.5. Their results show that the spectrum of pyroxene glass peaks at about 9.3 µm and 18 µm, providing the best fit to the silicate bands in the diffuse ISM and young stellar objects. A better match to the central wavelengths in RS Oph is provided by solid spheres of olivine glass, which shows peaks at 9.8 µm and 17 µm. (Ossenkopf, Henning & Mathis 1992) estimated the opacities of circumstellar silicates from sample spectra of 1

https://www2.mpia-hd.mpg.de/HJPDOC/
AGB stars and M-type supergiants. They give optical constants for warm O-deficient circumstellar dust and cool O-rich dust typical of OH/IR stars and the diffuse ISM. However, the data show considerable variation in the dust emission profiles, showing that there exists a range of dust properties. Therefore, the Ossenkopf, Henning & Mathis properties are only representative of circumstellar material.

This is problematic for modelling the silicate features, especially in RS Oph, as the longer wavelength peak occurs at 17\(\mu\)m, whereas the position occurs at 18\(\mu\)m in the stars considered by Ossenkopf, Henning & Mathis.

The central wavelengths and the relative band strengths are known to be effected by the degree of porosity. An increase in vacuum volume has the effect of decreasing the 18\(\mu\)m/9.7\(\mu\)m ratio and shifting the peaks toward longer wavelengths. Although models with porous grains could provide a better match to the central wavelength of the 9.7\(\mu\)m feature, they would provide an even worse match to the 18\(\mu\)m peak. Therefore, we only consider solid spheres in the following analysis and neglect the effects of porosity.

5.2 Dusty fitting

The DUSTY code solves radiative transfer for a dusty environment for a variety of grain compositions and size distributions (Ivezić, Nenkova & Elitzur 1999). We assume that the stellar wind is driven by radiation pressure on the dust grains. The dust is assumed to be spherically symmetric around the RS Oph system, although hydrodynamic simulations show that the wind density is 2-3 times larger in the binary plane than the average wind density in the system (Walder et al. 2008; Booth, Mohamed & Podsiadlowski 2016). This assumption may lead to overestimates for the mass-loss rate of the RG, but the hydrodynamic simulations are consistent with the observations for 10\(^{-7}\)\(M_\odot\) yr\(^{-1}\), which is within one order of magnitude of the values we derive below.
The radiation source is one of the main DUSTY inputs. For symbiotic stars, the main contributions are from the red giant, the white dwarf, the ionised nebula, the accretion disk, and the boundary layer (Skopal 2005). The variability of RS Oph over the course of the observations is a complicating factor for the analysis.

The SED is uncertain below 4000 Å, where the accretion disk and boundary layer dominate the emission. In the post outburst minimum, the red giant dominates above about 4000 Å and a hot component is present at shorter wavelengths. The contribution from free-free emission is already relatively small by that time. We use the results for the SED of the hot component, adopting a 25,000 K blackbody with a luminosity of $L = 370 L_\odot$. We use a model spectrum for the red giant companion, fitted to near infrared spectra from the post outburst minimum (Rushton et al. 2014; Pavlenko et al. 2016). The quiescent fluxes $F_\lambda$(total) were approximated by computing the contributions from the three principal components: $F_\lambda$(total) = $F_\lambda$(RG) + $F_\lambda$(AD) + $F_\lambda$(BL), where $F_\lambda$(RG) is the flux from the red giant, $F_\lambda$(AD) is an optically thick accretion disk, which radiates locally as a blackbody and $F_\lambda$(BL) is the contribution from the boundary layer (Skopal 2013; Pavlenko et al. 2016). The luminosities and characteristic temperatures are from Skopal (2013).

The best-fitting models were found with a routine executing DUSTY for several thousand combinations of input parameters, spanning a plausible set of values. The best-fit was found by calculating scaling parameters and the model with lowest $\chi^2$. The emission lines were removed from the data prior to fitting.

The main Dusty output parameters are the temperature at the inner edge of the dust envelope ($T_0$), the bolometric flux at the inner shell radius ($F_\lambda$) the optical depth at 0.55 μm ($\tau_{0.55}$), and the mass-loss rate (M). We assume a gas-to-dust ratio of 200 and a density for the grain material of 3 g cm$^{-3}$. For the mass-loss rate, the luminosity of the central source is used to scale the programme output from the value of $10^4 L_\odot$ assumed by Dusty (Ivezić, Nenkova & Elitzur 1999). We use the values from Skopal (2013) for the central source ($1.0 \times 10^3 L_\odot$ for 2006 and $1.7 \times 10^3 L_\odot$ for 2007-2009) at an assumed distance to RS Oph of 1.6 kpc (Hjellming & van der Marel 1999). The mass-loss rate scales with distance as $d^{3/2}$ (Ivezić, Nenkova & Elitzur 1999).

6 DISCUSSION

Table 2 shows in columns 2-6 the best-fitting parameters for each spectrum, along with the mass-loss rate, inner shell radius, and terminal outflow velocity determined by DUSTY. These last three parameters have been scaled from the assumed luminosity of $10^4 L_\odot$ using the values from Skopal (2013). The mass-loss rate and terminal velocity also depend on the assumed grain bulk density ($M \propto \rho^{1/2}$ and $v_{\infty} \propto \rho^{-1/2}$).

Figure 7 shows the best-fitting models to the spectra of RS Oph on the given dates. The goodness of the fits were evaluated for different grain compositions, and we found the best results with the O-deficient circumstellar dust as described by Ossenkopf, Henning & Mathis (1992). The largest discrepancy between the model and the data occurs because the 18 μm feature peaks at 17 μm in the data (see Fig. 8).

The dust temperature ($T_d$) is related to the luminosity of the source by $T_d^4 \propto L_{bol}/(Q_s)'$/($Q_{dust}'$, where ($Q_s'$) and ($Q_{dust}'$) are the planck mean emissivities at the temperatures of the radiating source and dust grains, respectively. During the period covered by the observations, the source output is highly variable, as the system recovers from the post outburst minimum and the accretion disk reforms. In quiescence, the source luminosity is less variable, explaining the modest variability in the last three datasets. The development of the UV emission, as the disk builds, is a possible reason for the narrowing of the 9.7 μm feature between 2006 and 2007, although there are few constraints on the emission at short wavelengths (see below).

The 2006 September 9 UT Spitzer spectrum has been...
The central wavelengths of the 9.7 \(\mu m\) and 18 \(\mu m\) features in RS Oph (red circles from Table 1) and symbiotics stars (black circles) from Angeloni et al. (2007). The dotted line is an empirical relation for symbiotic stars from Angeloni et al.

Figure 5.

The 6 – 10 \(\mu m\) region of RS Oph on 2006 September 9 (black line), and stellar model atmospheres showing SiO fundamental absorption. The models are computed at effective temperatures in the range 3800 – 4200 K, \(\log g = 1.0\), [C/H] = -0.8, [N/H] = 0.6 and microturbulent velocity \(V_t = 3\ \text{km s}^{-1}\) (Pavlenko et al. 2010).

Figure 6.

Spitzer IRS spectra of RS Oph on the dates shown. The red lines are DUSTY fits to the data. Previously modelled with DUSTY by Evans et al. (2007a). They obtained a reasonable fit with a higher dust temperature (T_d = 600 K) and larger optical depth (\(\tau_0.55 = 0.1\)) than we determine here. This is due to a different SED for the central source. Using a 3600 K blackbody, as used by Evans et al., we also obtain a reasonable fit for T_d = 600 K and \(\tau_0.55 = 0.1\). Rushton et al. (2010) also find a lower dust temperature (500 K) from fits to the excess at 3 – 5 \(\mu m\). Although Evans et al. (2007a) determine a higher dust temperature (600 K) from the 2006 September data, the inner shell radii in Table 2 (column 4) are in reasonable agreement with their value (1.5 × 10^{-14} cm) because they use a lower source luminosity.

The wind velocities in Table 2 (column 6) are lower than those determined from spectroscopy (45 km s^{-1} Shore et al. 1996; 33 km s^{-1} Iijima 2009), which may be due to the assumption of a spherical shell geometry. Although the wind velocity is unlikely to be constant, it would take about 800 days to reach the dusty region (for a wind velocity of 40 km s^{-1}). This means that there is a substantial lag before the dust envelope responds to changes in the outflow from the RG. Therefore, the decline in silicate emission could be a delayed reaction to the effects of the outburst on the secondary.

Table 2 (column 5) suggests that the mass-loss rate (as measured in the dusty region) is suppressed after 800 days, as the values are consistently lower in the last three datasets than they are in the first four datasets. Although this may be the case, we are hesitant to make this conclusion without better constraints on the temporal changes in the UV output of the 2006 eruption.

We have used model fits to the source SEDs from Skopal (2015), who included UV observations from the 1985 outburst, which lack temporal coverage in the late-eruption phase. The situation is similar for the 2006 outburst, with UV observations from the Neil Gehrels Swift observatory at few epochs for \(t = 200 – 1200\) days. This is a problem for the interpretation of the 2007 data. As the system climbs out of the post outburst minimum, the UV continuum develops, and a detailed description of the emission at all wavelengths is missing. Strong variability in the spectra at this time is indicative of large changes in the UV output. This suggests that the UV continuum stabilised at a late stage, and that the actual quiescent state was reached 597 < t < 804 days after the peak in the visual light curve.

During outburst, the RG is engulfed by the ejecta and the near-side is exposed to the radiation from the hot WD. The immediate effect is to increase the distance at which dust condensation is possible. Barry et al. (2008) showed that the sublimation radius reaches a maximum on about day 70 of the outburst and then steadily declines until about day 250 (about the time of the 2006 observations presented here). Although we can envisage a region behind the RG where the dust is shielded from the outburst (the shadow cone), the orbital motion of the star eventually leaves this material exposed to the hard radiation of the source. This would occur in just a few weeks (assuming the RG parameters in \(\S\)1 and the orbital parameters in Fekel et al. 2000) and well before the X-ray emission has subsided.

It is known that dust beyond the sublimation radius would survive the hard radiation of the eruption and the passage of the shock, making it a permanent feature of the sys-
tem (Evans et al. 2007). At a binary inclination of $i \sim 50^\circ$ (Brandi et al. 2009), there is unlikely to be any significant variation with orbital phase in the emission from this dust, but the observations reported here cover only about two orbits, and the geometry of the circumbinary material will vary as the RG wind refills the cavity created by the 2006 outburst. Therefore, the dust emission could be varying as grains form in the replenished gas. Although the Dusty fitting does not fully support the latter contention, in the form of an increase in $T_b$ and a decrease in $r_1$, a future analysis, incorporating an accurate description of the UV emission, may help to resolve this issue.

The data presented here show changes in the dust occurring at even later stages, into the recovery phase, as the hot component re-emerges at short wavelengths. Figure 5 shows that, in this period, $F_{\nu, 7\mu m}$ could be correlated with the visual brightness, peaking at the end of the recovery phase. The figure also shows the behaviour of the CO first overtone $\Delta \nu = 2 \rightarrow 0$ band head at $2.3\mu m$ (defined by the depth of the band head as a percentage of the continuum [CO%]; see Rushton et al. 2010). Interestingly, [CO%] is lower when the system is brighter and when $F_{\nu, 7\mu m}$ is higher. CO first overtone bands form in the upper atmosphere of late-type stars. They are sensitive to irradiation, appearing weaker as the effect increases. Their behaviour in RS Oph could be explained by the emergence of the hot component, heating the near-side of the RG. This may give rise to an anti-correlation between [CO%] and $F_{\nu, 7\mu m}$ (Figure 5), although better temporal coverage is needed to confirm that such a relationship exists. This could be achieved as the system returns to quiescence, following the 2021 eruption (lowest CO%)/highest $F_{\nu, 7\mu m}$ in 2023 March/April).

The Spitzer data show the presence of dust throughout the 2006-2009 period, even though the 3–5 µm excess disappeared in 2007, only to reappear by mid-2008 (Rushton et al. 2010). This could be due to variations in $T_d$ and the amplitude of the Wein side of the dust SED. However, the dust continuum is not significantly lower in the 2007 Spitzer data. This suggests that the stellar continuum is higher at this time, dominating the dust emission below 5 µm. The infrared photometry shows that there are times when the $(K - L_0)$ colour is stellar (about $(K - L_0) = 0.13$ for an early M giant; Ducati et al. 2001) as well as times when it shows the dust excess (Evans et al. 1988).

The mass-loss rate we derive is comparable to previous estimates, ranging from $M = 10^{-8} M_{\odot} \text{yr}^{-1}$ to $M = 10^{-7} M_{\odot} \text{yr}^{-1}$ (Tjinna 2008; Evans et al. 2007a; Shore et al. 1998). We emphasise that the values in Table 2 represent the material leaving the system and do not include any material accreted by the primary, although this is thought to be only a small fraction of the total mass lost by the red giant (Schaub et al. 2000).

The mass-loss rates in Table 2 are within the large range determined for symbiotic stars, ranging from $M = 10^{-9} M_{\odot} \text{yr}^{-1}$ to $M = 10^{-7} M_{\odot} \text{yr}^{-1}$ (Mikolajewska 2004). Multiple dust shells are common in D-type symbiotic stars, with several temperature components contributing to the IR continuum (Angeloni et al. 2007), unlike RS Oph, displaying just one dust component. IR excesses have been observed in two other symbiotic RN systems: V3980 Sgr and V745 Sco (Evans et al. 2014, 2022). They, too, can be fitted with one temperature component, suggesting similar circumstellar structures among the symbiotic RNs. V3980 Sgr shows only a weak IR excess, lacking silicate bands, whereas V745 Sco shows a strong IR excess, even stronger than the one observed in RS Oph (Evans et al. 2014). However, the dust properties in V745 Sco have yet to be constrained with IR spectroscopy.

7 SUMMARY

We have presented Spitzer IRS spectroscopy of the RN RS Oph, obtained on eight occasions after the 2006 outburst, covering the period from the post-outburst minimum, when the free-free emission from the nova ejecta has subsided, to the quiescent period, several hundred days after the peak in the light curve. The spectra are dominated by emission from dust in the wind of the RG and emission lines from shocked gas, in decline following the eruption.

The peak wavelength of the silicate features are environment dependent and the peak of the 9.7 µm band in RS Oph is at $> 10\mu m$, as is seen in other symbiotic stars. However, the 18 µm band peaks at 17 µm, which is shorter than those seen in symbiotics. Since RS Oph is a RN, a better comparison may be made with the symbiotic RN V745 Sco, which shows a significant IR excess due to dust in the wind of the secondary star.

The silicate dust features in RS Oph were fitted with the Dusty code, giving mass-loss rates of $1.0 - 1.7 \times 10^{-7} M_{\odot} \text{yr}^{-1}$. They are highly variable within the first 600 days of observation, appearing stronger in the 2006-2007 data than in the 2008-2009 data. In the earlier period, the system is emerging from the post outburst minimum, as the accretion disk, which is destroyed in the outburst, reforms.
and the UV output increases. We attribute to this process the behaviour of the silicate emission from that time. The reason for the subsequent decline in band strength is less clear, but it could be due to a reduction in either the mass-loss from the RG, or the UV radiation field. Further observations, following the 2021 outburst, could be used to determine the correct explanation.

ACKNOWLEDGEMENTS

We thank the anonymous referee for the constructive comments on this manuscript. We thank Andrew Helton for helpful discussions. This work is based (in part) on observations made with the Spitzer Space Telescope, which was operated by the Jet Propulsion Laboratory California Institute of Technology under a contract with NASA. We acknowledge with thanks the variable star observations from the AAVSO International Database contributed by observers worldwide and used in this research. RDG was supported by NASA and the United States Air Force. YP acknowledges support from grant 2017/27/B/ST9/01128 financed by the Polish National Science Center.

8 DATA AVAILABILITY

The data used in this paper are available from the Combine Atlas of Sources with Spitzer IRS Spectra (Lebouteiller et al. 2011, 2015).
