OBJECTIVE Few studies have been published specifically examining intravenous drug abuse (IVDA)–associated spinal epidural abscesses (SEAs), an unfortunate sequela of the opioid crisis in the United States. Here, the authors examined a series of patients with IVDA-associated SEAs in order to shed light on this challenging disease entity.

METHODS This study is a retrospective chart review of patients presenting with IVDA-associated SEAs at the authors' institution from 2013 to 2018, spanning the statewide implementation of opioid-prescribing restrictions.

RESULTS A total of 45 patients presented with IVDA-associated SEAs; 46.5% presented with a neurological deficit. Thirty-one patients underwent surgery for neurological deficit, failure of medical therapy, or both. Nineteen surgical patients underwent a fusion procedure along with decompression. The complication rate was 41.9%, and the mortality rate was 6.7%. The average length of stay was 27.6 days. Patients who underwent surgery within 24 hours of onset of neurological symptoms trended toward more improvement in their American Spinal Cord Association Impairment Scale grade than those who did not (0.5 vs –0.2, p = 0.068). Methicillin-resistant Staphylococcus aureus was isolated as the causative pathogen in 57.8% of patients. Twenty-three patients (51.5%) kept their scheduled clinic follow-up appointments. Of the fusion patients with adequate follow-up, 5 showed bony arthrodesis and 3 had pseudarthrosis. The rate of IVDA-associated SEAs increased after opioid-prescribing restrictions were put in place, from 0.54 cases per month to 1.15 cases per month (p = 0.017).

CONCLUSIONS Patients with IVDA-associated SEAs are challenging to treat, with high complication rates and poor follow-up. This disease is increasing in frequency, and opioid-prescribing restrictions did not slow that rise. Community outreach to promote prevention, early medical attention, and medication compliance would benefit this largely publicly funded patient population.

KEYWORDS intravenous drugs; epidural abscess; spine infection; opioid crisis
been described for some time, with Koeppel et al. presenting a series of 18 patients in the 1980s with IVDA-associated SEA. While diagnosis and treatment methods have evolved since that time, IVDA-associated SEA remains a challenging entity for clinicians. IVDA-associated spinal infections have been increasing, with a 2018 study by Blecher et al. showing a 3-fold increase in Washington state over the last 15 years.7 The patient population with IVDA-associated SEA is notorious for low compliance with medical care and poor follow-up.11,25,29,30 Consequently, little has been published specifically examining this group. We sought to examine a series of IVDA-associated SEAs from our tertiary-care, safety-net hospital in Southeastern Louisiana.

Methods

This retrospective chart review was approved by our institutional review board. The study period was July 2013 through July 2018. Patients at our tertiary-care, safety-net hospital (Interim LSU Hospital & University Medical Center New Orleans) were reviewed. Patients were queried for epidural abscesses using billing codes. A keyword search of “epidural abscess” within the radiology PACS (picture archiving and communication system) was also performed to ensure capture of all potential patients.

Charts were reviewed, and patients with recent intravenous drug use as a risk factor for epidural abscess were selected. These charts were reviewed for patient demographics, neurological examination findings, surgical intervention, perioperative complications, and outcome. Neurological examination findings were categorized according to American Spinal Injury Association Impairment Scale (AIS) with grades A–E assigned based on review of the initial presentation documentation. In patients who underwent fusion, fusion status was determined by either thin-slice CT or dynamic radiography.

Surgical intervention, both whether to intervene and which approach to use, was determined on a case-by-case basis by the attending neurosurgeon. Early surgery was defined as within 24 hours of presentation to the hospital, while late surgery was more than 24 hours after presentation. All cases were managed collaboratively with the internal medicine and infectious disease services.

The opioid prescribing policy for the state of Louisiana was obtained by querying the Louisiana Department of Health website.19 Louisiana drug use statistics were obtained by querying the Louisiana Department of Health website and the Center for Disease Control and Prevention website.2,3,19 The yearly incidence of epidural abscesses related to intravenous drug use was calculated using the total number of cases seen at our institution per 12 months. Comparison of the rate of epidural abscesses before and after Louisiana instituted opioid-prescribing restrictions was done using Fisher’s exact test.

Statistical analysis was performed using Microsoft Excel and SPSS; p < 0.05 was considered statistically significant.

Results

A total of 45 patients presented with an epidural abscess secondary to intravenous drug abuse. See Table 1 for a summary of demographics for this group. The ages ranged from 25 to 71 years, with a mean of 47 years; 34 patients (75.6%) were male. Medicaid was the payer in the majority of cases. Twenty-four patients (53.5%) presented without any neurological deficit, while 12 presented with AIS grade D, 6 with AIS grade C, and 2 with AIS grade B injuries, and 1 had a complete spinal cord injury. The lumbar spine was most commonly affected, with 22 patients having an abscess in that region; in 16 patients the cervical spine was involved, and in 10 the thoracic spine was involved. Two patients had undergone previous spine surgery, both involving instrumented fusions. These 2 patients both presented with abscesses associated with their prior instrumentation.

Thirty-one patients underwent surgical intervention. See Table 2 for a summary of the surgical characteristics for these patients. Sixteen patients (51.5% of surgical patients) underwent early surgery (within 24 hours). Twenty-two patients underwent surgery for a neurological deficit and 12 for failure of medical treatments. Medical therapy failed in 3 patients, and they developed new neurological deficits. Twenty-nine patients had a decompression and 19 of those also underwent fusion. Two patients with previous instrumented fusions underwent surgery to remove their instrumentation. They had both shown bony fusion on CT scans, and medical therapy to treat persistent abscesses had failed.

Thirteen patients (41.9%) had perioperative complications. Four patients required a return to the operating

| TABLE 1. Demographics of 45 patients with IVDA-associated SEAs |
|-------------------|------------------|
| Variable          | Value            |
| Mean age (range), yrs | 47.1 (25–71) |
| No. of males (%)   | 34 (75.6)        |
| Insurance, n (%)   |                  |
| Medicaid           | 30 (66.7)        |
| Medicare           | 7 (15.6)         |
| Uninsured          | 3 (6.7)          |
| Commercial         | 2 (4.4)          |
| Prisoner           | 3 (6.7)          |
| Initial AIS grade, n (%) |
| A                 | 1 (2.2)          |
| B                 | 2 (4.4)          |
| C                 | 6 (13.3)         |
| D                 | 12 (26.7)        |

| Thoracic          | 10 (22.2)        |
| Lumbar            | 22 (48.9)        |
| Mean duration of pain (range), days | 25.1 (2–90) |
| Underwent surgery, n (%) | 31 (68.9) |

* Spinal areas involved total to more than 100% because of patients with abscesses in multiple areas.
room for continued infection and fluid collections at the surgical site. Three had short-term instrumentation failure requiring revision. Three patients had intraoperative cardiac arrest, of whom 2 died postoperatively. One additional patient died of sepsis postoperatively, giving a mortality rate of 6.7%.

Of the patients undergoing decompression without fusion, all operations involved the thoracolumbar spine and a posterior approach was taken. Of the patients undergoing a decompression with fusion, 13 were cervical, 4 thoracic, and 2 lumbar. Four patients underwent an anterior approach only (all cervical). Eight had a posterior-only approach, and 6 underwent circumferential fusion.

Of the 21 patients who presented with a neurological deficit, 6 (28.6%) had improved at discharge. Four patients (8.9% of the total cohort) had worsening neurological deficits at discharge (including 2 patients who presented without any deficit). Patients who underwent surgery within 24 hours of presentation, on average, gained 0.2 grades on the AIS scale and those who underwent surgery after 24 hours declined 0.3 grades. This difference was not statistically significant (p = 0.068).

Length of stay ranged from 4 to 90 days, with an average of 27.6 days. Long-term acute care was the most common discharge destination, with 17 patients (37.8%) discharged there. Nine patients were discharged home, 4 to skilled nursing facilities, 3 to rehabilitation facilities, and 3 to custody. Six patients (13.3%) left against medical advice. See Table 3 for a summary of outcomes.

The most common bacterium isolated from intraoperative cultures, peripheral source, or interventional radiology biopsy was methicillin-resistant *Staphylococcus aureus* (MRSA; 26 patients [57.8%]). Methicillin-sensitive *Staphylococcus aureus* (MSSA) was present in 13 patients (28.9%), while streptococcal species were present in 2 patients and *Propionibacterium acnes* in 1 patient; 3 patients did not have any bacteria isolated.

Follow-up for these patients is extremely poor, as 13 patients (28.9%) did not have any follow-up. Only 23 patients followed up with their scheduled clinic visits, despite efforts to contact the remaining patients. An additional 9 patients stayed in contact with healthcare providers in our system by return visits to the emergency department. Fourteen patients (43.8%) who did undergo follow-up had confirmation of continued intravenous drug use. Only 8 of the 19 fusion patients had sufficient follow-up to determine fusion status. Five had confirmed fusion, and 3 had confirmed pseudarthrosis. See Table 4 for our follow-up statistics.

Drug-related deaths in Louisiana increased every year over our study period. The rate of epidural abscesses also showed an increasing trend line, although this rate is increasing more sharply than that of drug deaths (Fig. 3).

### TABLE 2. Characteristics of the 31 patients who underwent surgery for IVDA-associated SEAs

| Variable | No. of Patients (%) |
|----------|---------------------|
| Decompression | 29 (93.5) |
| Decompression & fusion | 19 (61.3) |
| Instrumentation removal only | 2 (6.5) |
| Surgical indication | |
| Neurological deficit | 22 (71.0) |
| Failed medical therapy | 12 (38.7) |
| Fusion level | |
| Cervical | 13 |
| Thoracic | 4 |
| Lumbar | 2 |
| Fusion approach | |
| Anterior only | 4 |
| Posterior only | 8 |
| Circumferential | 6 |
| Periop complications | |
| Washout for continued infection | 4 (12.9) |
| Short-term instrumentation failure | 3 (9.7) |
| Intraop cardiac arrest | 3 (9.7) |
| Death | 3 (9.7) |
| Fusion status | |
| Confirmed fusion | 5 (26.3) |
| Confirmed pseudarthrosis | 3 (15.8) |
| Insufficient follow-up | 11 (57.9) |

Total numbers for surgical indication add up to more than 100% due to 3 patients in whom medical therapy failed and a new neurological deficit developed during hospitalization.

### TABLE 3. Outcomes of patients presenting with IVDA-associated SEAs

| Variable | Value |
|----------|-------|
| Improved AIS grade at discharge, n (%) | 6 (28.6)* |
| Worse AIS grade at discharge, n (%) | 4 (8.9) |
| Bacteria isolated, n (%) | |
| MRSA | 26 (57.8) |
| MSSA | 13 (28.9) |
| Streptococcus spp. | 2 (4.4) |
| Propionibacterium acnes | 1 (2.2) |
| No growth | 3 (6.7) |
| Mean LOS (range), days | 27.6 (4–90) |
| Discharge location, n (%) | |
| Long-term acute care | 17 (37.8) |
| Home | 9 (20.0) |
| Skilled nursing | 4 (8.9) |
| Rehab | 3 (6.7) |
| Left AMA | 6 (13.3) |
| Prison | 3 (6.7) |
| Died | 3 (6.7) |

AMA = against medical advice; LOS = length of stay.

year. The rate of epidural abscesses before the restrictions
expanded to other patient populations over the rest of the
The restrictions were
initially comprised a 15-day supply limit for
 Medicaid fee-for-service patients. The restrictions were
expanded to other patient populations over the rest of the
year. The rate of epidural abscesses before the
restric-
tions on Medicaid fee-for-service patients were put into place
was 0.54 cases per month. This increased to 1.15 cases per
month after the restrictions were placed (Table 5). This
time.

Illustrative Case
This 55-year-old woman presented with 8 days of fever
and neck pain and a day of worsening left-sided weakness
and paresthesias. She experienced axial and neuropathic
pain but had near-complete resolution of her preoperative
weakness. Her CT scan at that time showed solid bony
arthrodesis (Fig. 3).

Discussion
Our series of 45 patients with IVDA-associated SEA
reiterates many of the follow-up and compliance chal-

gances faced by clinicians in other series. Wang et al.
published a series of 51 patients presenting with IVDA-as-
sociated spinal infections. They did not specify patients
with Sea. Forty-four patients in their cohort underwent
surgery. Their population showed similar difficulty with
compliance. Notably, 72.5% of their patients were ap-
prehended using intravenous drugs while in the hospital.

and paresthesias. She experienced axial and neuropathic
pain but had near-complete resolution of her preoperative
weakness. Her CT scan at that time showed solid bony
arthrodesis (Fig. 3).

Discussion
Our series of 45 patients with IVDA-associated SEA
reiterates many of the follow-up and compliance challenges faced by clinicians in other series. Wang et al. published a series of 51 patients presenting with IVDA-associated spinal infections. They did not specify patients with Sea. Forty-four patients in their cohort underwent surgery. Their population showed similar difficulty with compliance. Notably, 72.5% of their patients were apprehended using intravenous drugs while in the hospital. None of their patients maintained follow-up after 2 years. Ziu et al. reviewed 26 patients with IVDA-associated SEA. Twenty-two of these patients underwent surgery. Their patients had a slightly better follow-up, with 64.7% making a 1-year clinic follow-up appointment. The series by Chuo et al. out of Taiwan showed much better follow-up rates (100%) than the 2 American studies, but only included 3 cases of IVDA-associated SEA. In our series, only 51.1% of patients made 1 follow-up clinic visit. Of the patients who remained in contact with our healthcare system (either via clinic appointments or emergency department visits), 43.8% were still using intravenous drugs.

SEA, regardless of association with IVDA, is considered
a neurosurgical emergency. It can be treated medical
surgically. The majority of our patients (68.9%) underwent
neurosurgical intervention. The indications were neurological compromise or failure of medical management, which align with the existing literature.1,4-6,8,9,11,13,18,21,23,26,27,29,30 Our complication rates are similar to those of other studies covering this patient population. The study by Wang et al. reported several early hardware failures (15.9%) and recurrent infections (4.5%) requiring washout.29 Our rates were similar at 9.7% and 12.9%, respectively. Our in-hospital mortality rate was 6.7%, and the overall complication rate was 41.9%. This reflects the co-
morbidities that complicate care of these patients.

The majority of our patients (77.8%) had no change in their neurological examination results at discharge; 28.6% of the patients who presented with a deficit had improvement by the time of discharge. This contrasts the findings of Wang et al. (69% with improvement)29 and Chuo et al. (100% with improvement).31

A possible explanation for our lower rate of improve-
ment is the delays in medical care that many of our patients
experienced. Twelve of our patients with deficits had neu-
rological symptoms for 5 or more days before undergoing
surgical intervention. Reasons for delays included failure
to seek medical attention, noncompliance with physician
advice, and comorbidities precluding surgical intervention
(systemic sepsis or coagulopathy). Patients who underwent
surgery within 24 hours of onset of neurological deficits

| Variable                        | Value     |
|--------------------------------|-----------|
| Followed up in clinic, n (%)    | 23 (51.1) |
| Followed up in emergency depart-| 9 (20.0)  |
| ment, n (%)                     |           |
| Average follow-up, mos          | 10.6      |
| Confirmed still using intravenous drugs, n (%)* | 14 (43.8) |

* Percentage is based on the number of patients with any follow-up.
did have a slightly better chance at recovery of neurological function than those undergoing delayed surgery, but this result was not statistically significant. Of the 4 patients who had worse neurological examination results at discharge, 2 were initially treated medically and only underwent surgery after failure and new-onset deficits. The timing of surgical intervention in epidural abscesses is still one that is debated, although the literature does tend to favor early intervention.4,5,13 Our results also appear to favor early surgery, especially in light of the patients who had worse examination findings at discharge after medical therapy had failed.

The surgical approach for spine infections is also a controversial topic. Recent studies have allayed some of the fears regarding placing instrumentation in an infected field. Notably, the 2014 study by Bydon et al. showed no increased complication or reoperation rate for instrumented versus uninstrumented surgery on spine infections.10 However, only 15% of the patients in that study were intravenous drug users. Meanwhile, Wadhwa et al. showed that circumferential surgery for cervical osteomyelitis is associated with more complications than when it is done for myelopathy.28 It is difficult to determine the success of fusion in our population with such limited follow-up. We found that only 5 of 8 patients with adequate follow-up achieved bony fusion. Notably, these fusions were all in the cervical spine, where instrumentation is generally considered necessary. Of the patients with confirmed pseudarthrosis, 1 each had undergone lumbar posterior fusion, thoracic posterior fusion, and circumferential cervicothoracic fusion.

Regarding the causative pathogen, our series shows a much higher rate of MRSA than prior publications; 57.8% of our patients grew MRSA from intraoperative cultures, biopsy, or peripheral blood draws. This rate is higher than the MRSA rates in any of the prior studies we reviewed, both in IVDA- and non-IVDA-associated spine infections.5,13,30,31 This is likely a reflection of our patient population, as a strain of pathogen that is introduced into a network of intravenous drug abusers can create a community reservoir of that pathogen.14

As the only safety-net hospital in southeastern Louisiana, we are confident that our data capture most IVDA-associated SEAs in the metropolitan area. Our data show that there was a significant increase in the rate of epidural abscesses after Louisiana instituted restrictions on prescription opioids. One explanation for this would be that more people are turning to injectable opiates since they can no longer obtain pills. Another explanation is that this reflects the overall increasing trend, and our cutoff date is an arbitrary divide. Our increasing trend line does correlate with the increasing IVDA-associated spinal infections found by Blecher et al.7

Irrespective of the reason for its increasing rate, IVDA-associated SEA remains a significant public health issue. As we have shown here, these patients are extremely challenging to treat and consume large amounts of healthcare resources. We are not advocating for loosening opioid prescribing restrictions. Rather, this series highlights the need for better prevention efforts and community outreach to ensure timely access to care and compliance with follow-up. Simply being publicly funded in southeastern Louisiana is a risk factor for neurological infections,12 so this issue should be a high priority for policy makers.

Our study has many limitations, most notably the lack of consistent follow-up. Additionally, it is subject to the standard bias inherent in a retrospective review. However, even given these limitations, this series represents one of the largest covering IVDA-associated SEA.

Conclusions

IVDA-associated SEA is a challenging disease entity. Our patient population showed poor compliance and follow-up. Our series did demonstrate that early surgery can lead to neurological recovery. Additionally, instrumented fusion in the cervical spine can lead to bony arthrodesis

| Opioid Restrictions | Dates | Total Cases | Cases/Mo | p Value* |
|---------------------|-------|-------------|----------|----------|
| No                  | July 2013–January 2017 | 22 | 0.54 | 0.017 |
| Yes                 | February 2017–July 2018 | 23 | 1.15 | |

* Comparison made with Fisher’s exact test.

FIG. 3. CT scan obtained 1 year postoperatively, showing bony arthrodesis and stable instrumentation.
with fewer hardware failures than elsewhere in the spine. In addition, the rates of MRSA infection appear to be higher in our population than previously described in the literature. Lastly, our rate of IVDA-associated SEA has increased over the past few years. This increase correlates with state restrictions on opioid prescriptions.
