Abstract—Due to the importance for network operators of dynamically control networks (in contrast to what has been deployed until now), this paper proposes a technical solution based on an SDN architecture. With the introduction of an end-to-end (E2E) SDN architecture, it is possible to support an E2E service from access to backbone networks. This paper firstly presents an optimum end-to-end network architecture, which covers both network domains. A transport API is introduced (Control Orchestration Protocol protocol) and it is used for joint network orchestration between network controllers, in order to provide these E2E services. Finally, this paper presents a multi-partner demonstration, which involves two different labs, located in Telefonica and Trinity College of Dublin facilities. This demonstration is used to validate this work.

Keywords— SDN; PCE; ABNO; Network Orchestrator; Network Controller; Transport API; COP.

I. INTRODUCTION

Network operators have deployed their networks to cope with static services, where the traffic sources were clearly defined and they were not moving along the years. These types of services are changing and there is an important trend to deploy data centres to enable the deployment of application or virtual network functions (using network function virtualization – NFV). These new services and the expected continuous growth in Internet traffic (mainly driven by video) will imply a huge impact on the end-to-end (E2E) network. The network costs of current architectures depend significantly on traffic growth; the higher the traffic the higher the network costs. Consequently, any cost increase will impact on the ISP’s margins. The network architectures of the last 20 years were never designed to cope with these new types of service demands. Therefore, new architectural solutions are needed to deliver the huge expected increase in traffic in a cost-effective way, and ensure low cost broadband Internet access in Europe. The DISCUS project presents in [1] a metro-core node proposal to enable a most optimum E2E network architecture.

In order to have a dynamic node solution, it is mandatory to have a control plane that enables the configuration of the resources on demand. Software Defined Networking (SDN) proposes to decouple the control plane from the data plane to allow this dynamic operation. The utilization of SDN for access networks is motivated from operators [2], who are willing to have dynamic access networks to deploy new services. Recent works [3,4] have presented SDN demonstration in access networks.

Moreover, the utilization of GMPLS in core optical networks has allowed having a SDN ready solution for the backbone network. The appearance of Path Computation Element (PCE) and Application Based Network Operation (ABNO) architecture allows having a SDN solution for fix and flexi grid networks. There are recent works [5, 6] demonstrating the dynamic provisioning of services in backbone networks, considering multi-layer and multi-technology environments.

This paper defines and demonstrates an architecture to support E2E service from access to backbone. The remaining of the article is structured as follows. Section 2 introduces the DISCUS metro/core node architecture. Section 3 defines the SDN architecture to allow end-to-end services. This work uses the Control Orchestration Protocol, which is presented in Section 4. Section 5 introduces the use case that motivate the work. Section 6 presents the experimental validation and the results. Finally, Section 7 concludes this article.

II. METRO/CORE NODE ARCHITECTURE

The DISCUS metro/core nodes are core edge nodes in a similar architectural position in the network to what are often called metro-core nodes in classic telecommunication architectures. The DISCUS Metro/Core node are the only nodes in the network covered by a single optical island with traffic processing functions. The architecture of these nodes is flexible enough so that different (IP, Ethernet and Optical) layers can evolve and if necessary displace other layers minimising cost and energy consumption. The node architecture consists of an optical switching layer, an Ethernet layer and an IP layer. The optical switch provides flexible interconnect between theses layers and the optical channels from the access and core networks. The large port-count
optical switch allows maximum flexibility as any incoming fibre can be terminated, after demultiplexing, at any OLT, or can be re-amplified and sent back to another ONU or regenerated and sent over the optical core network. Since every access PON can carry a large number of wavelengths, potentially 80 or more in the medium to long term, the optical switch must be highly scalable, while offering a very low optical loss (less than 2-3dB). The Optical Switch should have large switch matrices and a potentially be 3-stage switches capable of scaling to over 12000 ports.

An access network controller is associated to every metro/core node, where it controls the optical switch, access switch, and OLTs/ONUs. The access controller sends abstracted topological information about the resources available within its domain. Where access protection is required, the controller handles incoming failure messages from the OLT to operate fast protection. Moreover, the access controller receives provisioning requests from the orchestrator and reports the service setup status. Finally, the access controller should be able to carry out path computation, because the network orchestrator can request a path computation. To do so, the physical domain information have to be obtained from the network elements and mapped in the abstracted view. Similarly, the provisioning of abstracted services is map in real configurations. Therefore, the access controller maintains information on bandwidth availability within the access switch and each OLT. Besides, it configures the network elements (access switch, optical switch, OLT, ONU/ONT), depending on its specific requirements.

III. SDN ARCHITECTURE TO ALLOW E2E SERVICES

The SDN control plane architecture is shown in Fig. 2, and it is based on a hierarchical structure of controllers. This architecture is aligned with Open Network Foundation (ONF) work. Three main logical components can be identified for the SDN control plane. The access network controller, in charge of controlling the access network elements; the backbone network controller, in charge of controlling the elements carrying out backbone transmission and the network orchestrator, in charge of taking requests from application plane and translating them into high-level commands for the access and backbone network controllers.

In terms of interfaces, the overall architecture follows the ONF architecture using three main interfaces: A-CPI, I-CPI and D-CPI. The A-CPI interface describes the interaction between the control plane and the application plane. Thus is the interaction between the service provider and the network orchestrator. The I-CPI interface operates between the network orchestrator and the access and core network controllers. Lastly, the D-CPI interface operates between the access and backbone controllers and the physical devices. There are different protocols to cope with the functionalities in each interface. The demonstration in this work has selected a set of protocols to fulfill the requirements in each domain aligned with the industry trends.

A. Network Orchestrator

The network orchestrator is defined as a parent controller or a centralized “controller of controllers”, which handles the automation of end-to-end connectivity provisioning, working at a higher, abstracted level and covering inter-domain aspects between the access and the metro/core network. The network orchestrator interfaces with the controllers to get topological information about the resources in each controller’s domain. Each controller may have different interfaces, which requires the orchestrator to have a method to support multiple technologies or interfaces.

When an application, such as Network Management System (NMS) or Operation Support System (OSS) requests a service, the network orchestrator must deal with the end-to-end path computation and service request. This process can be done by the orchestrator or delegated to the access and backbone controllers. Once the services are set-up, the network orchestrator is in charge of update its status and notify to the application plane.

B. Access Network Controller

The DISCUS SDN Access Network Controller (NC) show in Fig. 3 translates requests from the Network Orchestrator (NO) into instructions for the physical devices, such as access switch, optical switch and OLT. The NC consists of JSON (REST/API), Application module, Database, and RYU controller. The JSON (REST/API) module is an interface that
In the FPGA hardware. The OLT and connected ONUs can be various changes to the PON network via a UART control link coming from the Access Network controller and communicates PON OLTs and ONU. This interprets the openflow commands native openflow network devices such as the FPGA-based LR-optical switch, access switch and PON components. We have various network components in the access network, such as the Access Network controller uses openflow to manage the address of a primary OLT (if the device is an ONU). The shows the IP address of the host; PRI_OLT_IP shows an IP number of the host (it could be an SP server, ONU, or OLT); ip address for each numbered host. host_id indicates the ID of the primary OLT (if the device is an ONU). The Access Network controller uses openflow to manage the various network components in the access network, such as the optical switch, access switch and PON components. We have devised an Openflow Agent that provides a mediation interface with the nodes is Path Computation Element Protocol (PCEP), as demonstrated in [5].

In brief, the COP is composed of three main base functions:

1) **Topology service**, which provides topological information about the network, including a common and homogeneous definition of the network topologies included in the Traffic Engineering Databases (TED) of the different control instances;
2) **Path computation service**, providing an interface to request and return path objects which contain the information about the route between two endpoints;

3) **Call service**, based on the concept of Call/Connection separation, and providing a common provisioning model which defines an end-to-end connectivity provisioning service.

The COP definition is open for discussion and can be downloaded and contributed at [https://github.com/ict-strauss/COP](https://github.com/ict-strauss/COP).

The **Topology Service** provides abstracted topological information about the network. It must include a common and homogeneous definition of the network topologies included in the TED of the different control instances. The COP Topology provides the interface for the exchange of detailed network topology between SDN controllers. An abstract Topology object may consist of a set of nodes and edges, which form a tree structure. A Node must contain a list of ports/endpoints and their associated switching capabilities (e.g., packet/lambda switch capable). An Edge object is defined as the connection link between two Endpoints, which includes some traffic metrics and characteristics. Due to the need of conforming to a common model among different transport network technologies, the definition of the three main objects described (Node, Edge, Endpoint) must be extensible, able to include TE extensions to describe different switching capabilities (i.e., time-slots, packets, wavelengths, frequency slots).

The **Call service** is defined in the scope of COP as the provisioning interface of each domain SDN controller. The Call is defined as the API's basic data-container and it completely solves the provisioning of an End-to-End connectivity service. A Call object describes the type of service that is requested or served by it (e.g., DWDM, Ethernet, MPLS). It also contains the endpoints between whom the service is provided. The Call object also includes the list effective connections made into the data plane, to support the service call. Moreover, a Call also includes a list of traffic parameters that need to be supported, such as Quality of Service, or allocated bandwidth. Finally, a Call shall include the Match parameter, which refers to the traffic description to which the Call refers. A Connection object is used for a single network domain scope. It should include the path object (i.e., the route) across the network topology the data traverses, which may be fully described or abstract depending on the orchestration/control schemes used. Each connection must be associated with a single control plane entity (e.g. a SDN controller) responsible for the configuration of the data path. Finally, the Call also introduces the necessary TE parameters (e.g., bandwidth) that the service requests.

Both the Topology and Call services can be extended in order to not only provide abstracted information, but to provide low level technological dependant details, such as optical spectrum grid or CIR/PIR.

Finally, the **Path Computation** service should provide an interface to request and return Path objects, which contain the information about the route between two Endpoints. Path computation is highly related to the previous group of resources. In the service Call, the Connection object has been designed to contain information about the traversed Path. Furthermore, each component in the Path object is represented as an Endpoint with TE information associated to it.

V. **USE CASE FOR DEMONSTRATION**

The Use Case shown in Fig. 4 exemplifies how capacity constraints in the Core and Access Metro network of a Telecommunications network may be overcome both in terms of restoration of QoS but also opportunistically for the dynamic temporary provision of high bandwidth services. In the Metro Access network, we implement a DWA mechanism that can facilitate allocation of capacity (an entire wavelength or a portion of a TDM-PON channel) to specific PON users on a dynamic and temporary basis, with applications for on-demand multimedia and big data transfers. Alternative scenarios envisaged include the reapportionment of wavelength bandwidth throughout the PON network by time of day, week or month. In the cases of temporary and dynamic migration of wavelength it is important that the wavelength switching time is minimized to avoid impacting users of other network services. In Step 1, an end user (customer) elects through a portal frontend to the ABNO controller to transmit a fixed bandwidth transport (100Mbps) between two end points aEnd (10.0.50.3) and zEnd (10.0.50.4) typically for the sending and receipt of Video streaming. In Step 2, the ABNO orchestrates the provision of the path, according to its knowledge of the full End to End topology covering the Core and Metro Access Networks. The Idealist core backbone NC and the Metro Access (DISCUS) SDN NC, are each instructed to provision an explicit path in steps 3 and 4 respectively. For the Metro Access portion of the network (the path from 10.0.50.2 to 10.0.50.4), the DISCUS SDN NC is instructed to provision the path according to the route 10.0.50.2 to 10.0.50.1 to 10.0.50.4. The DISCUS SDN Controller provisions the path through the Metro Access (openflow) switch (step 5), and the PON (primary/secondary OLT and ONU – step 6). Using a custom implemented PLOAM message, the primary OLT requests the ONU tune to a wavelength provisioned out of the secondary OLT (step 7). In step 8, the DISCUS SDN NC, acknowledges that it has completed the provisioning of the path through the Metro Access portion of the network. In step 9, the Video transmission is triggered to start.

VI. **EXPERIMENTAL VALIDATION**

A. **Test-bed**

There are two different labs set-up to demonstrate the scenario of this work one in Telefonica premises and another in Trinity College of Dublin. Fig. 4 shows a schema of the lab set-up for this experiment. To communicate them, there is a VPN created, so the data plane connection has a low bandwidth.
The network orchestrator is located in Telefonica labs and is based on netphony ABNO implementation. The north and south-bound interface of the orchestrator is implemented using the STRAUSS COP. The backbone controller uses the netphony ABNO, which in addition with netphony PCE controls a GMPLS emulated control plane. The GMPLS nodes uses the protocol suite developed by Telefonica I+D and is released in github. This setup is built with 30 virtual machines, which run in a Linux server distribution. Each emulated node implements a GMPLS stack (including RSVP, OSPFv2 and PCEP) with the extensions to support flexgrid developed in IDEALIST project.

The LR-PON Protocol is implemented over three Xilinx VC709 FPGA boards acting as primary and secondary OLTs and ONU. The LR-PON protocol is a partial implementation of the XGPON standard, the major differences being that the LR-PON protocol must work over a longer feeder fiber (125Km in LR-PON as opposed to 20Km in XGPON) and across a higher split ratio (512 versus 64). The PON backplane connection to the core network contains a 10G Ethernet physical layer and Media Access Control Layer, allowing it to be plugged into any 10G capable network element. In this experiment the PON backplane is connected to a 48-port 10G Openflow Access/Metro switch. A Microblaze soft processor, which is collocated on the Virtex FPGA board, provides a (North Bound) UART management interface to the PON OLT and ONU hardware. Through this interface most PON functionality can be controlled such as resetting the hardware, viewing hardware status, simulating hardware failure, loading bandwidth map and setting XGEM mappings. Dynamic Wavelength Assignment is supported through the addition of laser and filter control to the LR-PON protocol hardware and control mechanisms. The tunable laser is controlled across an i2c bus to the Skylane 10G SFP+ tunable lasers and the tunable filter is controlled through a UART. To implement DWA in the physical layer, we employ a splitter and filter in the downstream, and a WSS (Optimum 9x1/1x9 50Ghz Wavelength Selective Switch) in the upstream direction, statically patched to ITU channels 32.5 and 31 of the primary and secondary OLT respectively. In order to select the OLT and ONU transmission wavelengths, the OLT provides a North Bound interface. Through this Interface, the control plane can tune an OLT’s transceivers to a given wavelength. Since the ONU is remote from the control plane, tuning of an ONU’s laser and filter can be performed also through this interface by the invocation of custom PLOAM message within the LR-PON protocol. The wavelength of the OLT and ONU may be selected by writing to control registers in the OLT. Each individual OLT laser wavelength can be set by writing the target ITU channel number to its local register. To select the wavelength of transmission for an ONU, the ITU channel number is set by writing the target ITU channel number to register of the OLT to which it is homed. The ONU Id must also be specified so as to distinguish an individual from multiple ONU’s homed off a single OLT.

For the experimental LR-PON access network, the configuration is comprised of a Pronto 3780 switch with 48 10G interfaces, running release 2.4 (Openflow v1.4 compatible firmware). The Pronto switch is configured with multiple virtual bridges.

A Video Server (VLC) application is co-located with the ABNO controller interface in the Telefonica premises. This transmits a UDP based video stream across the Tunnel between the two testbeds, traversing the DISCUS PON and being received by the GPU workstation for display by the TV display. The latency between the two testbeds was measured over 100 measurements at between 45 and 48 ms. It was not possible to transmit the video stream through the Idealist network, as a physical DataPath was not available.

B. Workflow steps in the architecture

This section explains step by step how this demonstration is performed (Fig. 4). First, the portal requests a new video service, which cannot be processed within the access area scope. This means that there is a request of the video platform to provisioning an end to end path between the client and the video server. Therefore, the STRAUSS ABNO receives a COP calls service set-up to establish the connection. The STRAUSS ABNO carries out a path computation, which crosses different networks, the backbone (IDEALIST) and access network (DISCUSS). Therefore, the STRAUSS ABNO sends a COP calls service set-up to each controller to configure the nodes in their domain. The IDEALIST PCE configures the GMPLS nodes, while the DISCUS controller configures the access elements. The workflow is explained in Fig. 5.

C. Results

The previous workflow was demonstrated in the lab set-up. Fig. 6 shows the message exchange between the different elements.

![Message exchange diagram]

Fig. 6. Whisreshark capture

As it is shown in Fig. 6, the ABNO receives an HTTP POST request with request parameters. The aEnd and zEnd router IDs identifies the client and the video server. The traffic parameters are set to request a 100Mbps connection and a 100 ms latency. This request is sent as an Ethernet service.

Once the STRAUSS ABNO receives the requests asks its PCE for a path computation between the two end points. To do so a PCReq-PCResp process is performed. Now, the PCE can calculate the path and response to ABNO with a PCResp, which contains the Explicit Route Object with the path. The ABNO controller with the ERO information call to Provisioning Manager (PM) via a PCInitiate message. The PM split the route in different domains and with a COP message call to each controller to create a path in each domain (IDEALIST and DISCUS). When the path is created each controller send respective http message with an OK status. With this information PM response to ABNO controller with a PCEReport message and finally ABNO report to video platform with an HTTP response.

![JSON object for a COP service-call set-up]

Fig. 7. JSON object for a COP service-call set-up

Across 10 repetitions of the experiment, the total completion time of the workflow was measured at 275ms. Of this, 35 ms (with associated inter-testbed latency) related to the blocking element of the call to the DISCUS SDN Controller. The non-blocking elements of the DISCUS SDN proceed in parallel with the completion of the return calls by the ABNO controller.

VII. CONCLUSIONS

The network costs of current architectures depend significantly on traffic growth. The DISCUS project presents in a metro-core node proposal to enable a most optimum end-to-end network architecture, but it requires the interaction with a backbone solution like the flexgrid technologies of IDEALIST.

This work defines and demonstrates an SDN architecture to support end-to-end service from access to backbone. The validation work has involved two laboratories and thanks to this work, we can claim that network operators can deploy SDN solutions that covers, not only access or backbone scenarios, but also end to end.

ACKNOWLEDGMENT

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n. 318137 in DISCUS project, in. 317999 in IDEALIST research project and no 608528 by the Japanese Ministry of Internal Affairs and Communications (MIC) and National Institute of Information and Communications Technology (NICT) through the EU-Japan coordinated project STRAUSS.
