ABSTRACT

We present results from Spitzer Space Telescope observations of the mid-infrared phase variations of three short-period extrasolar planetary systems: HD 209458, HD 179949 and 51 Peg. We gathered Infrared Array Camera (IRAC) images in multiple wavebands (3.6 or 4.5 and 8 μm) at eight phases of each planet’s orbit. We find the uncertainty in relative photometry from one epoch to the next to be significantly larger than the photon counting error at 3.6 and 4.5 μm. We are able to place 2σ upper limits of only ∼2 per cent on the phase variations at these wavelengths. At 8 μm, the epoch-to-epoch systematic uncertainty is comparable to the photon counting noise and we detect a phase function for HD 179949 which is in phase with the planet’s orbit and with a relative peak-to-trough amplitude of 0.00141 (3σ). Assuming that HD 179949b has a radius $R_1 < R_p < 1.2R_J$, it must recirculate less than 21 per cent of incident stellar energy to its night side at the 1σ level (less than 26 per cent at the 2σ level, where 50 per cent signifies full recirculation). If the planet has a small Bond albedo, it must have a mass less than 2.4 $M_J$ (1σ). We do not detect phase variations for the other two systems but we do place the following 2σ upper limits: 0.0007 for 51 Peg and 0.0015 for HD 209458. Due to its edge-on configuration, the upper limit for HD 209458 translates, with appropriate assumptions about Bond albedo, into a lower limit on the recirculation occurring in the planet’s atmosphere. HD 209458b must recirculate at least 32 per cent of incident stellar energy to its night side, at the 1σ level (at least 16 per cent at the 2σ level), which is consistent with other constraints on recirculation from the depth of secondary eclipse depth at 8 μm and the low optical albedo. These data indicate that different hot Jupiter planets may experience different recirculation efficiencies.

Key words: methods: data analysis – techniques: photometric – stars: planetary systems.

1 BACKGROUND

1.1 Introduction

Since the discovery of the first hot Jupiter system (Mayor & Queloz 1995) and the subsequent realization that such systems are ubiquitous (Butler et al. 2006), astronomers have struggled to observe these planets and to compare these observations to theoretical predictions about their surface temperature variations, composition, albedo and internal structure. The observations of extrasolar planetary transits, starting with HD 209458b (Charbonneau et al. 2000; Henry et al. 2000), have allowed for the determination of the mass and size of these planets, but it was only with the observation of secondary eclipses, starting with HD 209458b (Deming et al. 2005) and TrES-1 (Charbonneau et al. 2005), that it has been possible to measure the flux from these planets (for a review of transiting exoplanet science see Charbonneau et al. 2007). The depth of the secondary eclipse, however, only characterizes the day-side flux from the planet. To fully characterize the planet’s longitudinal temperature profile, observations must be made at a variety of planetary phases. The first such observations were reported by Harrington et al. (2006) and Knutson et al. (2007). In this paper, we present similar observations of three other planetary systems. We briefly review models of hot Jupiter phase variations in Sections 1.2 and 1.3, and the observational constraints in Section 1.4. In Section 2 we present our observations and in Section 3 we explain how they constrain the properties of hot Jupiters. We state our conclusions in Section 4.

1.2 Toy model

For the purposes of this paper, the phase function of a planetary system is taken to be the relative flux contribution from the planet as a function of its orbital position. Here, we describe a toy model of hot Jupiters

*E-mail: cowan@astro.washington.edu
†Alfred P. Sloan Research Fellow.

Jupiter phase functions, based on a planet in a circular orbit with two isothermal hemispheres and neglecting the planet’s remnant heat of formation, an effective temperature of $T_{\text{eff}} \approx 50$–75 K (Burrows, Sudarsky & Hubeny 2006). The Bond albedo, $A_B$, is the fraction of the incident stellar flux that is reflected by the planet. A planet’s energy budget is largely determined by its Bond albedo. Hence, if we treat the host star as a blackbody, the equilibrium temperature of a planet’s day and night faces is, respectively,

$$T_{\text{day}}^4 = (1 - A_B)(1 - P_a) \left( \frac{R_p^2}{2a^2} \right) T_{\text{eff}}^4$$

and

$$T_{\text{night}}^4 = (1 - A_B)P_a \left( \frac{R_p^2}{2a^2} \right) T_{\text{eff}}^4,$$

where $R_p$ and $T_{\text{eff}}$ are the star’s radius and effective temperature, $a$ is the planet’s semi-major axis and $P_a$ quantifies the portion of the absorbed stellar energy advected to the planet’s night-side ($P_a = 0$ for no redistribution; $P_a = 0.5$ for full redistribution) (Burrows et al. 2006).

The depth of secondary eclipse (for edge-on systems) is approximately the ratio of the planet’s day-side flux, $F_{\text{day}}$, to the stellar flux, $F_\star$. In light of the models of Fortney et al. (2006), we assume that the planet’s day and night-side radiate as blackbodies $F = B(T)$ and that the host star emits with a mid-IR brightness temperature $T_{\text{bright}}$ (we use $T_{\text{bright}} = 0.87T_{\text{eff}}$ at 8 µm based on the models of Kurucz 1979). The resulting planet–star flux ratio is

$$F_{\text{day}} = \frac{F_\star}{A_B} \left( \frac{R_p}{R_\star} \right)^2 + \frac{B(T_{\text{day}})}{B(T_{\text{bright}})} \left( \frac{R_p}{R_\star} \right)^2,$$

where $R_p$ is the planetary radius and the ratios $R_p/a$ and $R_p/R_\star$ can be well-constrained, if the planet transits its host star. The wavelength-dependent geometric albedo, $A_B$, is the ratio of the total brightness of the planet at full phase to that of a Lambertian disc with the same cross-section. The second term (thermal emission from the planet) can be neglected at optical wavelengths.

In the infrared, we may neglect the contribution from reflected starlight. The peak-to-peak amplitude of the phase function for a transiting systems then becomes

$$\frac{F_{\text{day}} - F_{\text{night}}}{F_\star} = \frac{B(T_{\text{day}}) - B(T_{\text{night}})}{B(T_{\text{bright}})} \left( \frac{R_p}{R_\star} \right)^2,$$

where $F_{\text{night}}$ is the flux from the planet’s night-side and where we have neglected the planet’s flux contribution (<1 per cent) in the denominator. Note that the absolute flux from the planet is a minimum during the secondary eclipse, irrespective of phase variations, since the planet is entirely hidden from view at that time. The normalized phase variations, $\Delta F(\phi)/(F)$, for a system with inclination $i$ is

$$\Delta F(\phi) = -\sin i \cos \phi \frac{F_{\text{day}} - F_{\text{night}}}{2F_\star},$$

where $\phi$ is the planet’s orbital phase ($\phi = 0$ at inferior conjunction; $\phi = \pi$ at superior conjunction) and $(F)$ is the time-averaged flux of the system.

Measurements of secondary eclipse depth thus constrain a combination of $A_B, A_g$ and $P_a$ in this toy model. Observations of the phase function amplitude constrain these same parameters, as well as $\sin i$ and $R_p$ in the case of non-transiting systems.

1.3 Numerical models

In addition to the toy model outlined above, there have been numerous more sophisticated attempts to model the atmospheres of hot Jupiters and thus to predict the depth of secondary eclipses as well as the full phase function of specific extrasolar systems. We summarize the most pertinent aspects of these models here (for a more thorough background see Burrows et al. 2006). Cooper & Showman (2005, 2006) determine energy recirculation and predict global temperature contrasts of ~500 K at the photosphere. They also predict a notable offset between the phase function peak and the time of opposition. Fortney et al. (2005) construct models with either no or full recirculation and find that the latter is a better fit to secondary eclipse observations. Burrows, Hubeny & Sudarsky (2005), Barman, Hauschildt & Allard (2005) and Seager et al. (2005) also run simulations with different amounts of recirculation and find that significant redistribution of heat must be occurring to explain the observations. Fortney et al. (2006) run models to calculate emitted spectra as a function of orbital phase for both equilibrium and non-equilibrium chemistry. They find that non-equilibrium chemistry leads to significantly smaller phase variations and that current observations can be explained with a blackbody-like planetary spectrum. Finally, Burrows et al. (2006) use the factor $P_a$ to characterize the efficiency of energy recirculation and construct models for five different values of the parameter. They find that current observations rule out models with no recirculation and are in fact consistent with full recirculation (although they admit that current observations are not precise enough to determine the exact degree of recirculation).

1.4 Observational constraints

Secondary eclipses have been reported for four short-period extrasolar planetary systems and a phase function has been reported in a different, non-transiting system. We summarize these results below. Richardson, Deming & Seager (2003) placed an upper limit of $3 \times 10^{-4}$ on the relative secondary eclipse depth at 2.2 µm using the SpeX instrument at the NASA Infrared Telescope Facility. The secondary eclipse of HD 209458, observed with the Multiband Imaging Photometer for Spitzer (MIPS) yielded a relative depth at 24 µm of 0.0026 ± 0.0004 (Deming et al. 2005). Similarly, the secondary eclipse of TrES-1 was observed in the IRAC 4.5- and 8-µm bands, yielding eclipse depths of 0.00066 ± 0.00013 and 0.00225 ± 0.00036, respectively (Charbonneau et al. 2005). The latest system to have been detected in secondary eclipse is HD 189733 (Deming et al. 2006). Observations with the Spitzer Infrared Spectrograph (IRS) peak-up imager at 16 µm give an eclipse depth of 0.0051 ± 0.0003. In addition to infrared detections, the non-detection of a secondary eclipse for HD 209458 at optical wavebands has constrained the 500 nm secondary eclipse depth to be less than $4.88 \times 10^{-5}$ at the 1σ level and less than $1.34 \times 10^{-4}$ at the 3σ level (Royer et al. 2006). Ground-based K-band (2.2 µm) observations of OGLE-TR-113b tentatively show a secondary eclipse depth of 0.0017 ± 0.0005 (Snellen & Covino 2007). MIPS 24 µm imaging of ν Andromedae has yielded a phase function with peak-to-trough amplitude of 0.0029 ± 0.0007 and weak evidence of a small phase offset (Harrington et al. 2006). This surprisingly large amplitude suggests that the planet has parameters $A_B \approx 0, P_a \approx 0$ and $i \approx 30^\circ$. Continuous IRAC 8-µm monitoring of HD 189733 for half of a planetary orbit led to the detection of a phase function with a peak-to-trough amplitude of 0.001123 (4) (Knutson et al. 2007). This modest phase function, roughly one third the relative depth of secondary eclipse, indicates that much of the incident stellar energy is being recirculated to the planet’s night side. Grillmair et al. (2006) used IRS to obtain a mid-IR spectrum for HD 189733b, which showed no evidence for absorption bands due to either water or methane. Richardson et al. (2007) obtained the

Note: The wavelength of the observations is \( \lambda \), \( \tau_{\text{exp}} \) is the duration of a single exposure, \( N_{\text{exp}} \) is the number of exposures per nod, \( \tau_{\text{nod}} \) is the total time on target per nod, \( F_s(\sigma) \) is the average flux of the system and the associated error, while \( \Delta F_s(F) \) is the \( 2\sigma \) upper limit, or the best-fitting peak-to-trough amplitude and associated \( 1\sigma \) uncertainty for phase variations, as appropriate.

relative mid-IR spectrum of HD 209458b and similarly concluded that such absorption features could be excluded; they also identified candidate emission features at two wavelengths.

2 DESCRIPTION OF OBSERVATIONS

2.1 Photometry

We acquired Spitzer photometry\(^1\) with the IRAC 3.6 or 4.5 \( \mu m \), and 8-\( \mu m \) detectors in subarray mode (32 \( \times \) 32 pixel, or 38.3 \( \times \) 38.3 arcsec\(^2\)) to avoid saturation (Fazio et al. 2004). Observations were made at eight different phases for each planetary system with follow-on time constraints. Each observation consists of four nods to the target star interleaved with four nods to a nearby flux standard of comparable infrared brightness. The number and duration of exposures for each of our targets are summarized in Table 1. We convert fluxes from the Spitzer units of specific intensity (MJy sr\(^{-1}\)) to photon counts, and use aperture photometry to recover the counts for the science and standard stars. We determine the PSF centroid using a centre-of-light function, then use the Interactive Data Language (IDL) routine Aperture photometry (APER) to extract the source flux. After testing many combinations of aperture and sky annulus radii for robustness, we settle on a 7 pixel aperture radius and a sky annulus centred on the target star, with an inner radius of 10 pixel and an outer radius of 15 pixel.

2.2 Calibration

A single observation lasts only 20 min, compared to planetary orbital periods of days, so the flux is not expected to vary notably within a single observation. Unfortunately, the measured signal in the 3.6- and 4.5-\( \mu m \) bands exhibits large (a few per cent) fluctuations. The pointing drifts between nods are subpixel, yet other researchers have found that the IRAC 4.5 \( \mu m \) indium antimonide (InSb) array shows significant intra-pixel sensitivity variations (Charbonneau et al. 2005; Morales-Calderón et al. 2006). The 3.6 \( \mu m \) detector, also an InSb array, likely suffers from the same problem. We do not have sufficient images to properly map out the position-sensitivity relation, and this severely limits the quality of our 3.6 and 4.5 \( \mu m \) data. The 8 \( \mu m \) observations of 51 Peg and HD 179949 show a smooth increase in gain, with a similar shape for both the science target and flux standard, indicating an instrumental effect, as shown in Fig. 1. HD 209458, a somewhat fainter source, does not exhibit such a marked ramp-up. The illumination-dependent nature of this instrumental effect, described in greater detail in Knutson et al. (2007), is consistent with charge trapping, in that pixel sensitivities are initially deficient but asymptote to a constant value as the pixels are illuminated repeatedly.

For each observation, we determine the total counts by multiplying the median count by the number of frames, thus ignoring the minority of frames affected by cosmic rays. We repeat this median averaging for all the exposures within each nod (with duration \( \tau_{\text{nod}} \)) and take the standard deviation in the counts from each exposure multiplied by the square root of the number of exposures per nod to be the uncertainty in the total counts. We find these uncertainties to be four to five times larger than the expectation from Poisson noise at 3.6 and 4.5 \( \mu m \), and roughly twice the Poisson noise at 8 \( \mu m \). At the shorter wavebands, as well as for the 8 \( \mu m \) observations of HD 209458, the points from different nods show considerable scatter but no obvious trend, so we add up the counts from all the nods separately for the science and reference star, and then take the ratio of the two sums to determine the relative flux at that epoch.

Noting that the ramp-up at 8 \( \mu m \) for 51 Peg and HD 179949 levels off towards the end of any given observation, we take the ratio of the summed counts for the two final nods as the relative flux at that epoch. In all cases, we compute the uncertainty in the flux ratio by taking the quadratic sum of the relative uncertainties in the science and standard counts. The average flux measured for each star can be found in Table 1.

3 LIGHT CURVES AND IMPLICATIONS

We use ephemerides from Butler et al. (2006), for which projected errors at the epochs of our observations are less than 60 min for all three systems. We neglect the correction for the light travel time

\(^1\) Cycle 2 Spitzer program GO 20482, PI Agol.
across the Solar system, since the size of this correction (less than 8 min) is less than the uncertainty in the orbital phase. By matching the planet phases with the relative flux at that epoch, we construct a relative light curve for each system, shown in the top panel of Figs 2–4 (the 3.6 and 4.5 μm light curves are not plotted due to prohibitively large systematic uncertainties). HD 179949 and 51 Peg are non-transiting systems, while the observations of HD 209458 were taken outside of transit or secondary eclipse (represented by shaded areas in Fig. 4).

We use a 10^5-step Markov chain Monte Carlo with Metropolis–Hastings algorithm (Ford 2005) to determine the best-fitting sinusoid, which is shown as the curve in the top panel of Figs 2–4. The amplitude and constant offset of the sinusoid are allowed to vary, while the period is fixed at 2π and the phase offset is set to zero, in accordance with Section 1.2, as well as the results of Harrington et al. (2006). None of the 3.6 and 4.5 μm light curves, or indeed the 8 μm light curve for 51 Peg or HD 209458, shows a variation that is better fit by a sinusoid than a straight line. We do, however, detect an 8 μm phase function with peak-to-trough amplitude of 0.0031 we would expect for an edge-on planet with a radius of 1.2R_*, an albedo of 0 and a recirculation parameter of P_n = 0. For the two systems where we do not detect a phase function, the Markov chain produces the cumulative distribution functions shown in Figs 5 and 6. These plots show the full range of theoretically allowed phase function amplitudes for this system.

8 μm light curve for 51 Peg or HD 209458, shows a variation that is better fit by a sinusoid than a straight line. We do, however, detect an 8 μm phase function with peak-to-trough amplitude of 0.001 41 (33) for HD 179949, compared to an amplitude of 0.0031 we would expect for an edge-on planet with a radius of 1.2R_*, an albedo of 0 and a recirculation parameter of P_n = 0. For the two systems where we do not detect a phase function, the Markov chain produces the cumulative distribution functions shown in Figs 5 and 6. These plots show the full range of theoretically allowed peak-to-trough phase function amplitudes for this system.

We recognize that ν Andromeda and HD 179949 are the only two planet-bearing systems studied by Shkolnik et al. (2005) to...
Constraining the planetary radius to within constrains the properties of this system, as explained in Section 1.2. At least the year they observed it, the observed phase variation places a 1σ upper-limit of \( P_n < 0.2 \). Further constraining the albedo to \( A_B = 0 \), consistent with the value of \( A_b = 0.03(5) \) that Rowe et al. (2007) measured for HD 209458b, we obtain the exclusion plot shown in Fig. 7. Our model thus places a 1σ limit of \( M < 2.4M_j \) on the mass of HD 179949b.

Because of the edge-on configuration of HD 209458, our upper limit can be combined with the constraint on the planet/star radius exhibit chromospheric activity in phase with the planetary orbit. It is therefore possible that the mid-IR phase variations that have been observed in these systems are a consequence of stellar activity and not the diurnal flux contrast of the planet. We do not believe that chromospheric activity is responsible for the phase function we observe in HD 179949, however, as the cycle in chromospheric activity Shkolnik et al. (2005) observed in this system was 60° out of phase with the planetary orbit, and this pattern persisted for at least the year they observed it.

If the phase variation of HD 179949 is taken at face value, it constrains the properties of this system, as explained in Section 1.2. Constraining the planetary radius to within \( R_1 < R_p < 1.2R_j \), the observed phase variation places a 1σ upper-limit of \( P_n < 0.21 \). Further constraining the albedo to \( A_B = 0 \), consistent with the value of \( A_b = 0.03(5) \) that Rowe et al. (2007) measured for HD 209458b, we obtain the exclusion plot shown in Fig. 7. Our model thus places a 1σ limit of \( M < 2.4M_j \) on the mass of HD 179949b.

4 CONCLUSIONS

We have acquired Spitzer IRAC 3.6 or 4.5 and 8 μm images of three known hot Jupiter systems. The use of standard stars has allowed us to achieve better than 0.05 per cent relative photometry with multi-epoch IRAC 8 μm observations. Intra-pixel sensitivity variations limit our photometry at 3.6 and 4.5 μm. We detect an 8-μm phase function for HD 179949 and determine upper limits for the amplitude of phase variations in the two other observed systems. We analyse these light curves using a toy model of the planets and constraining the properties of the planets. Our observations suggest that hot Jupiters do not all exhibit the large mid-infrared diurnal flux contrast detected by Harrington et al. (2006). Even within our modest sample of three planets, it appears that HD 179949b and HD 209458b exhibit rather different degrees of recirculation. The data for HD 179949 and \( \nu \) Andromeda provide the most uncertain constraints, however, while the two transiting systems with well-constrained phase functions (HD 209458 and 189733; Knutson et al. 2007) both point toward a large value of \( P_n > 0.35 \), so it remains to be seen if the observations of the non-transiting planets hold up under further scrutiny.
