The detectability of cosmological gravitational-wave backgrounds: a rule of thumb

The recent claim by BICEP2 of evidence for primordial gravitational waves from inflation has focused interest on the potential for early-Universe cosmology using observations of gravitational waves. In addition to cosmic microwave background detectors, efforts are underway to carry out gravitational-wave astronomy over a wide range of frequencies including pulsar timing arrays (nHz), space-based detectors (mHz), and terrestrial detectors (10–2000 Hz). This multiband effort will probe a wide range of times in the early Universe (each corresponding to a different energy scale), during which gravitational-wave backgrounds may have been produced through processes such as phase transitions or preheating. In this letter, we derive a rule of thumb (not quite so strong as an upper limit) governing the maximum energy density of cosmological backgrounds. For most cosmological scenarios, we expect the energy density spectrum to peak at values of $\Omega_{gw}(f) \lesssim 10^{-12\pm2}$. We discuss the applicability of this rule of thumb and the implications for gravitational-wave astronomy.

Extrapolating the BICEP2 measurement to the LIGO band, we expect $\Omega_{gw}(f) \approx 10^{-15}$. GW backgrounds at this level are too weak to observe directly except by the most ambitious detectors [2] and, of course, using the cosmic microwave background [1].

However, cosmological signals, produced through other mechanisms, can produce considerably more detectable signals with $\Omega_{gw} \lesssim 10^{-12}$. Detection of a cosmological background above the level predicted for the amplification of vacuum fluctuations could point to a richer and more interesting early Universe than posited by the simplest version of slow-roll inflation.

Here, we draw attention to generic features common to many cosmological backgrounds in order to derive a “rule of thumb” governing the maximum likely amplitude of most cosmological backgrounds. We use the phrase “rule of thumb” rather than “upper limit” to convey the theoretical uncertainty in our derivation. The rule of thumb employs assumptions consistent with a large number of models in order to provide a broadly (if not universally) applicable prediction governing the maximum energy density of cosmological backgrounds. The point is to provide a systematic framework for understanding trends among predictions of cosmological backgrounds.

Our rule of thumb applies to backgrounds (at all energy scales) created after inflation during the radiation-dominated epoch. During this epoch, the age of the Universe varied between $10^{-35}s \lesssim t \lesssim 47000$ yr, corresponding to energy scales of $10^{15}$ GeV $\lesssim E \gtrsim 1$ eV, and redshifts $z \gtrsim 3500$. We assume that the length scale of the source is smaller than the cosmological horizon $H^{-1}$, which follows from causality. Our rule of thumb does not apply to astrophysical backgrounds, which can peak well above cosmological models [12], as they are created at much later times.

We assume that the background evolves as a Friedmann-Lemaitre-Robertson-Walker spacetime. GWs
propagate as strain perturbations $h_{ij}$ in synchronous gauge,
\[ ds^2 = dt^2 - a^2(t) [\delta_{ij} + h_{ij}] \, dx^i \, dx^j, \]
where the propagating degrees of freedom are the two polarizations that obey the transverse-traceless conditions,
\[ h^i_i = 0 \text{ and } h^i_{ij} = 0. \]
These strain perturbations obey sourced Klein-Gordon equations,
\[ \ddot{h}_{ij} + 3H \dot{h}_{ij} - \frac{1}{a^2} \nabla^2 h_{ij} = (16\pi G) S_{ij}^{TT}, \]
where the source is the transverse-traceless projection of the anisotropic stress tensor,
\[ S_{ij}^{TT} = T_{ij} - \frac{\delta_{ij}}{3} \bar{T} k. \]

Our objective is to estimate $\Omega_{gw}(f)$ from a relatively generic cosmological source. To this end, we link GW energy density $\rho_{gw}$ to the energy density of some source $\rho_s$, which, in turn, represents some fraction of the total energy density in the Universe $\rho$. By considering the fraction of energy density available for the source, and the fraction of the source energy density converted to GWs, we estimate the maximum $\Omega_{gw}(f)$ today.

We make a few assumptions about the source. We consider a source associated with a characteristic scale $k_*$, and assume that components of the stress-energy tensor can be written in momentum space as
\[ \hat{T}_{ij}(\vec{k}) \approx \bar{T}(\vec{k}) = A \exp \left[ \frac{(|\vec{k}| - k_*)^2}{2\sigma^2} \right], \]
where each $T_{ij}(k)$ is approximately the same magnitude, $\sigma$ parameterizes the source width, and $A$ is the peak height. Although $A$ is determined by the detailed physics of each source, it cannot exceed the total energy density of the Universe at the time of the process.

The isotropic pressure of the source,
\[ \hat{p}_s(\vec{k}) = \frac{1}{3} \left( \bar{T}_{11}(\vec{k}) + \bar{T}_{22}(\vec{k}) + \bar{T}_{33}(\vec{k}) \right) = \bar{T}(\vec{k}), \]
is related to the energy density of the source,
\[ \hat{\rho}_s(\vec{k}) = \frac{\hat{p}_s(\vec{k})}{w} = \frac{\bar{T}(\vec{k})}{w} \]
by $w$, which relates the magnitude of the stress-energy tensor of the source to the source energy density. If we chose a volume large enough so the configuration-space energy density is homogeneous, we can use Parseval’s theorem to relate the momentum space spectrum to the total source energy in a volume $V$,
\[ \int d^3k \left| \hat{\rho}_s(\vec{k}) \right|^2 = \int dV \rho^2_s(\vec{x}) \approx V \rho^2_s. \]

We define
\[ W(k_*, \sigma) \equiv 4\pi \int_0^\infty k^2 \exp \left[ -\frac{(k - k_*)^2}{\sigma^2} \right] \, dk. \]
The magnitude of the stress-energy tensor and the source energy density are related:
\[ |A|^2 = \frac{w^2 \rho^2 \bar{V}}{W(k_*, \sigma)}. \]
The GW energy created in this process is only a fraction, $\alpha < 1$ of the total energy budget of the Universe: $\rho_s = \rho$. Thus,
\[ \left| \bar{T} \right|^2 = \frac{w^2 \alpha^2 \bar{V} \rho^2}{W(k_*, \sigma)} \exp \left[ -\frac{(k - k_*)^2}{\sigma^2} \right]. \]

Next, we calculate the size of the metric perturbations. Since each mode $h_{ij}(k)$ obeys a sourced Klein-Gordon equation (assuming that the source is short-lived compared to the Hubble time, allowing us to momentarily ignore the Hubble Friction term), we estimate the maximum size of $h_{ij}$ by studying the point when the acceleration of $h_{ij}(k)$ vanishes. In the language of a harmonic oscillator, we evaluate the size of the metric perturbation by balancing the force due to the source with the restoring force. It follows that the $h_{ij}$ are approximately the same:
\[ \ddot{h} \approx \dot{\bar{T}} = \frac{16\pi G}{k^2} S^{TT}. \]

Last, we relate the size of the transverse-traceless anisotropic stress tensor to the size of the stress-energy tensor:
\[ \beta = \frac{\left| S^{TT} \right|^2}{\left| T \right|^2}. \]
The projection of $T_{ij}$ onto $S^{TT}_{ij}$ extracts the tensor-part of the stress-energy tensor and is therefore sensitive to the source geometry. This is the hardest parameter to estimate without specific knowledge of the source.

We determine the magnitude of $A(\vec{k})$, but not the phase, necessary to estimating $\beta$. One realization of $A_{ij} = A e^{i\theta_{ij}}$ has six independent phases. We randomly chose six phases and project the stress-energy tensor $T_{ij}$ onto the transverse-traceless anisotropic stress tensor $S^{TT}_{ij}$ generating a distribution of $\beta$. Using a simulation, we determine $\beta \approx 10^{-1.5} - 10^{-2}$ for a random process.

We use
\[ \Omega_{gw}(k) = \frac{k^3}{32\pi G} \frac{1}{V} \sum_{i,j} \int d\Omega \left| \dot{h}_{ij}^{TT}(t, k) \right|^2 \]
to calculate $\Omega_{gw}(k)$ at the time when the source vanishes. We exchange numerical factors for the sum in Eq 15 and evaluate the angular part of the integral,
\[ \sum_{i,j} \int d\Omega \left| \dot{h}_{ij} \right|^2 = 36\pi \left| \dot{h} \right|^2. \]
where

\[ |\dot{h}|^2 = |\dot{T}|^2 = (16\pi G)^2 \left( \frac{\beta}{k^2} \right)^2 \]

(17)

via Eqs. 13 and 14. We combine Eq. 17 with Eq. 16 and plug into Eq. 15 yielding

\[ \Omega_{gw}(k) = \frac{288\pi^2 G}{\rho \nu} k_\beta \left| \dot{T} \right|^2 = \frac{108\pi}{\rho \nu} H^2 k_\beta^2 |\dot{T}|^2, \]

where the final equality follows from Friedmann’s equation:

\[ H^2 = \frac{8\pi G}{3\rho}. \]

(19)

When the source vanishes,

\[ \Omega_{gw}(k) = \frac{108\pi \alpha^2 \beta w^2}{W(k_\sigma, \sigma)} H^2 k_\beta \left[ -\frac{(k-k_\sigma)^2}{\sigma^2} \right]. \]

(20)

It might seem surprising that we can write this spectrum so simply. In particular, Eq. 20 depends on the dimensionless quantity \( H^2 k_\beta W(k_\sigma, \sigma) \), and so we need not know the scale \( k_\sigma \). The peak energy density can be estimated by evaluating

\[ \Omega_{gw}(k_\sigma) \approx 108\pi \alpha^2 \beta w^2 N(k_\sigma, \sigma). \]

(21)

Last,

\[ N(k_\sigma, \sigma) \equiv \frac{H^2 k_\sigma}{W(k_\sigma, \sigma)} = \frac{\left( k_\sigma H^{-1} \right)}{W(k_\sigma H^{-1}, \sigma H^{-1})}. \]

(22)

We investigate Eq. 22 numerically. For fixed \( k_\sigma \), \( N(k_\sigma, \sigma) \) diverges as \( \sigma \to 0 \), but only for unphysically small values of \( \sigma \). Generally, the source width can be a few orders of magnitude smaller than the characteristic frequency. Nonetheless, decreasing the source width changes the amplitude of the GW spectrum modestly. For small values of \( \sigma/k_\sigma \),

\[ N(k_\sigma, \sigma) \ll \left( \frac{k_\sigma}{\sigma} \right). \]

(23)

In practice, we expect that \( \sigma < k_\sigma \), so we estimate \( N(k_\sigma, \sigma) \) by setting the ratio of \( \sigma/k_\sigma \). In the small \( \sigma/k_\sigma \) limit,

\[ N(k_\sigma, \sigma) \to 0.0449 \left( \frac{k_\sigma}{\sigma} \right) \left( \frac{H}{k_\sigma} \right)^2, \]

(24)

where the proportionality constant is obtained evaluating \( W(k_\sigma, \sigma) \) numerically.

In present times, \( \Omega_{gw,0}(k) \)

\[ \Omega_{gw,0}(k) \approx 2.3 \times 10^{-4} \alpha^2 \beta w^2 \frac{k_\sigma}{\sigma} \left( \frac{H}{k_\sigma} \right)^2. \]

(28)

(This scaling is noted in \( 29, 31 \)). Now, we identify plausible values of \( k_\sigma/H \) and \( \sigma/k_\sigma \). In principle, \( k_\sigma/H \) is different for different cosmological processes. However, given our goal of constraining the maximum allowable \( \Omega_{gw} \) from cosmological sources, we chose a value, as small as possible so that \( N(k_\sigma, \sigma) \) is as large as possible, subject to constraints from causality: the peak wavelength must be sub-horizon. Motivated by models of bubble collisions \( 32, 33 \) and phase transitions \( 20, 21, 34 \), we chose fiducial values \( k_\sigma = 100H \), and \( \sigma/k_\sigma = 1/2 \). (While a large class of models employ comparable parameters, other choices can be made for specific models—e.g., \( 28, 32 \)—which can be investigated with Eq. 28). We thereby obtain our rule of thumb:

\[ \Omega_{gw,0}(k) \approx 4.7 \times 10^{-8} \alpha^2 \beta w^2. \]

(29)

If we repeat the above calculations assuming that \( \dot{T}(\tilde{k}) \) is described, not by a Gaussian distribution as in Eq. 6 but by a plateau distribution, [constant on \( (k_\sigma - \sigma, k_\sigma + \sigma) \) and zero everywhere else], then the resulting rule of thumb prediction is just 9% less. Thus, the results do not depend strongly on the assumed shape of \( \dot{T}(\tilde{k}) \).
Equipped with Eq. 29, we consider three different scenarios—corresponding to three sets of tunable parameters \((\alpha, \beta, w)\) reflecting the plausible range of \(\Omega_{\text{gw}}(k_*)\). These scenarios, described in Tab. I, are labeled “optimistic,” “realistic,” and “pessimistic.” These categorizations, inspired by 36, are necessarily subjective. However, by providing a range of values, we endeavor to show a range of possible outcomes. For the realistic scenario, the rule of thumb becomes: \(\Omega_{\text{gw},0}(k_*) \approx 1 \times 10^{-12}\).

| scenario | \(\alpha\) | \(\beta\) | \(w\) | \(\Omega_{\text{gw}}(k_*)\) |
|----------|---------|---------|-------|--------------------------|
| optimistic | 1.0 | 0.1 | 0.03 | \(4.97 \times 10^{-10}\) |
| realistic | 0.1 | 0.03 | 0.03 | \(1.49 \times 10^{-12}\) |
| pessimistic | 0.03 | 0.001 | 0.005 | \(9.93 \times 10^{-15}\) |

TABLE I: Energy density peak heights for three sets of tunable parameters assuming \(\sigma/k = 1/2\) and \(k_*/H = 100\).

We now assess the detectability of the three representative rule-of-thumb signals using different GW detectors. We consider: (i) Advanced LIGO using 1 yr of coincident Hanford-Livingston data at design sensitivity, (ii) the proposed Einstein Telescope using 1 yr of coincident data with the “ET-D” sensitivity 37, (iii) a hypothetical pulsar timing array from 38 consisting of 20 pulsars and assuming 100 ns timing noise, 5 yr of observation time, and a cadence of 20 yr\(^{-1}\), and (iv) the Big Bang Observer (BBO) 39, 40, a proposed space-based detector using parameters from 38.

For each detector, we optimistically tune the peak frequency \(f_* \equiv ck_*/2\pi\) to produce the most favorable signal. The results are summarized in Fig. 1. The rule-of-thumb signals (thin dashed) are compared to the sensitivity curve for each detector (solid). The sensitivity curves are “power-law integrated curves” 38, representing the sensitivity of each detector to a broadband stochastic background with a power-law shape.

While the GW signals we consider here are peaked, not power laws, the power-law integrated curves nonetheless provide a useful guide. Any dashed rule-of-thumb line falling below the solid power-law integrated curve is undetectable. Dashed lines intersecting the solid power-law integrated curve might be detectable, and when this happens, we calculate the signal-to-noise ratio (SNR) of a two-detector, cross-correlation search 41.

From Fig. 1, all three \(f_* = 23\) Hz rule-of-thumb spectra are out of reach for Advanced LIGO. The optimistic spectrum can perhaps be probed with additional detectors and/or multiple years of coincident data. The Einstein Telescope detects a highly significant \(f_* = 6.5\) Hz signal from the optimistic spectrum while the realistic spectrum produces a marginal SNR = 3.2 detection. The pessimistic spectrum is out of reach. Our hypothetical pulsar timing array unambiguously detects the optimistic \(f_* = 6.8\) nHz spectrum (SNR = 19), but not the realistic or pessimistic spectra. BBO detects statistically significant \((f_* = 0.15\) Hz) signatures from all three; SNR > 380. Note: we have ignored complications arising from correlated noise 42 and the subtraction of astrophysical foregrounds 40, 43, which may complicate detection.

Our rule of thumb applies to a large subset of cosmological GW sources that occur after inflation and during the radiation-dominated epoch. The argument presented here, after all, relies solely on the ratio of three energy density scales, \(\rho_{\text{gw}} < \rho < \rho_{\text{cr}}\), and on the application of transfer functions. There are, however, exceptions.

In non-minimal models of inflation 14, 44, 45, signals evade our bounds because they are “frozen in” during phase transitions. GWs remain non-dynamical until they re-enter the horizon when the Universe cools to the appropriate temperature, and so the ratio of energy density scales is irrelevant. Another possible modification to inflation involves the introduction of direct couplings between the inflaton (usually an axion field) and gauge fields 47, 48. As inflation ends, one polarization of the gauge field is dramatically enhanced via a tachyonic process and inflation ends earlier than in canonical slow-roll inflation. These modes efficiently decay into GWs.

A non-standard equation of state following inflation might lead to a detectable cosmological background. In particular, a “stiff” equation of state \(w > 1/3\) modifies the expansion history of the Universe, allowing...
inflationary gravitational radiation to re-enter the horizon with large amplitudes \cite{49}. This model evades our rule of thumb since the source is not a post-inflationary cosmological process. However, as pointed out in \cite{49}, there is no theoretical motivation for an effective equation of state larger than 1/3 after inflation.

If the graviton is not a massless, helicity-2 particle (see, e.g. \cite{50,51}) this analysis needs to be rethought in the presence of extra degrees of freedom. In these models, it is likely that the GW background would be less diluted when the source is projected, leading, potentially, to a greater value of $\beta \approx 1$. Thus, it may be easier for GW observatories to detect cosmological backgrounds in non-standard theories of gravity \cite{52}.

Cosmic string networks produced during phase transitions in the early Universe \cite{53} can produce GWs in the late Universe via strong bursts of GWs produced from cusps \cite{56}. The peak wavelength of these signals is tied to the size of the cosmic strings, not the Hubble scale, and the background is produced at fairly late times (even though the strings themselves are formed very early). If cosmic string networks were to radiate gravitationally during the radiation-dominated era, these signals would be subject to the constraints presented here, where $k_a \gg H$ (since strings are small compared to the Hubble scale) likely corresponding to very weak signals today.

Our knowledge of the early Universe is far from precise, and GW astronomy affords us the chance to learn more about this important era. The coming decades are likely to produce a flood of observational GW data, which will constrain cosmological models and possibly reveal unknown physics. As we prepare for this upcoming era of GW cosmology, it is useful to consider our expectations for what we think we might reasonably detect, based on our present knowledge of the early Universe. To this end, we have proposed a simple rule of thumb governing the maximum amplitude of cosmological GW backgrounds: we expect cosmological backgrounds to produce energy density spectra that peak around $\Omega_{gw} \approx 10^{-12}$. Our rule of thumb is based on simple scaling arguments and provides robust, if approximate, theoretical guidance for GW cosmology.

In order to evade the rule-of-thumb assumptions models typically employ assumptions about inflationary dynamics that require some degree of fine tuning. We argue that, based on our current understanding of the early Universe, the simplest, most natural models predict cosmological GW backgrounds that follow the rule of thumb. The rule of thumb does not apply to astrophysical backgrounds since they are created after matter/radiation equality. Finally, we note that observational constraints from Big Bang nucleosynthesis and the cosmic microwave background limit the integrated energy density of cosmological backgrounds; see, e.g., \cite{54,55}.
