Abstract

The semi-exponential basis set of radial functions (A.M. Frolov, Physics Letters A 374, 2361 (2010)) is used for variational computations of bound states in three-electron atomic systems. It appears that semi-exponential basis set has a substantially greater potential for accurate variational computations of bound states in three-electron atomic systems than it was originally anticipated. In particular, the 40-term Larson’s wave function improved with the use of semi-exponential radial basis functions now produces the total energy $-7.4780581457$ a.u. for the ground $1^2S$–state in the $\infty$Li atom (only one spin function $\chi_1 = \alpha\beta\alpha - \beta\alpha\alpha$ was used in these calculations). This variational energy is very close to the exact ground state energy of the $\infty$Li atom and it substantially lower than the total energy obtained with the original Larson’s 40-term wave function ($-7.477944869$ a.u.).

I. INTRODUCTION

In this study we perform variational calculations of bound states in three-electron atomic systems. A basis set of semi-exponential radial functions [1] is extensively used in our calculations. The main goal is to solve the non-relativistic Schrödinger equation $H\Psi = E\Psi$, where $E < 0$ and bound state wave function $\Psi$ has the unit norm. The general non-relativistic Hamiltonian $H$ of the three-electron atomic problem is (see, e.g., [2])

$$H = -\frac{\hbar^2}{2m_e} \left[ \nabla_1^2 + \nabla_2^2 + \nabla_3^2 + \frac{m_e}{M} \nabla_4^2 \right] - \frac{Q e^2}{r_{14}} - \frac{Q e^2}{r_{24}} - \frac{Q e^2}{r_{34}} + \frac{e^2}{r_{12}} + \frac{e^2}{r_{13}} + \frac{e^2}{r_{23}}$$  \hspace{1cm} (1)

where $\hbar = \frac{\hbar}{2\pi}$ is the reduced Planck constant, $m_e$ is the electron mass and $e$ is the electric charge of electron. In this equation and everywhere below in this study the subscripts 1, 2, 3 designate the three electrons $e^-$, while the subscript 4 denotes the heavy nucleus with the mass $M$ ($M \gg m_e$) and positive electric (nuclear) charge $Q e$. The notations $r_{ij} = | \mathbf{r}_i - \mathbf{r}_j | = r_{ji}$ stand for the six interparticle distances (= relative coordinates) defined in an arbitrary four-body system and $\mathbf{r}_i$ ($i = 1, 2, 3, 4$) are the Cartesian coordinates of the four point particles. In Eq. (1) and everywhere below in this work we shall assume that $(ij) = (ji) = (12), (13), (14), (23), (24), (34)$. Below only atomic units $\hbar = 1, | e | = 1, m_e = 1$ are employed. In these units the explicit form of the Hamiltonian $H$, Eq. (1), is significantly simplified.

The main attention in this work is focused on numerical calculations of the ground (doublet) $1^2S(L = 0)$—state (or $1^2S_\frac{1}{2}(L = 0)$—state) of the three-electron Li atom with the infinitely heavy nucleus, i.e. the $^\infty$Li atom. Considerations of other three-electron atoms, ions and various positron containing atomic systems (e.g., HPs) can be performed absolutely analogously (for more detail, see [1]) and, therefore, these systems will not be considered here.

The problem of highly accurate calculations of the bound states in three-electron atomic systems has attracted continuing attention. The first calculations of the Li atom with the truly correlated wave functions were performed in 1936 [3]. A brief reviews of such calculations can be found in [4] (earlier works) and [5] (references up to 1997 are mentioned). The current bibliography on this subject includes almost one thousand references and is increasing rapidly. The classical Hylleraas method (see, e.g., [3]) is the method capable of predicting the most highly accurate wave functions for bound states of three-electron atomic
systems. In this method to produce the most highly accurate wave functions (e.g., for the ground (doublet) \( 1^2S \)-state in the Li atom) one needs to use many thousands of Hylleraas basis functions. The use of extremely large basis sets is very inconvenient in many actual cases, since it produces a number of computational problems. It is clear that the classical Hylleraas method cannot be used to construct both compact and accurate variational wave functions for three-electron systems. Indeed, it contains essentially no control parameters which can be optimized by increasing the overall efficiency of the method.

An alternative approach to variational bound state calculations in three-electron atomic systems was proposed in [1]. This approach is based on the use of semi-exponential variational wave functions [1] and it allows one to construct very compact and accurate variational wave functions for arbitrary three-electron atomic system. Each of the semi-exponential basis functions depend upon all six interparticle coordinates \( r_{12}, r_{13}, \ldots, r_{34} \) [1]. A high efficiency of this new approach in actual applications and its superiority over the classical Hylleraas expansion was demonstrated in [1]. As follows from the results of this study the semi-exponential basis set has a substantially greater potential for highly accurate variational computations of bound states in three-electron atomic systems than it was anticipated earlier [1].

II. VARIATIONAL WAVE FUNCTION

The variational wave function of the doublet \( S(L = 0) \)–states of the three-electron Li atom is written in the following general form

\[
\Psi_{L=0} = \psi_{L=0}(A; \{r_{ij}\})(\alpha \beta \alpha - \beta \alpha \alpha) + \phi_{L=0}(B; \{r_{ij}\})(2\alpha \alpha \beta - \beta \alpha \alpha - \alpha \beta \alpha) \tag{2}
\]

where \( \psi_{L=0}(A; \{r_{ij}\}) \) and \( \phi_{L=0}(B; \{r_{ij}\}) \) are the two independent spatial parts (= radial parts) of the total wave function. Each of these two radial functions is, in fact, a radial factor (for states with \( L = 0 \)) in front of the corresponding three-electron spin functions \( \chi_1 = \alpha \beta \alpha - \beta \alpha \alpha \) and \( \chi_2 = 2\alpha \alpha \beta - \beta \alpha \alpha - \alpha \beta \alpha \). Here the notations \( \alpha \) and \( \beta \) are the one-electron spin-up and spin-down functions, respectively (see, e.g., [6]). The notations \( A \) and \( B \) in Eq. (2) mean that the two sets of non-linear parameters associated with radial functions \( \psi \) and \( \phi \) can be optimized independently. In the general case, each of the radial basis functions explicitly depends upon all six interparticle (relative) coordinates \( r_{12}, r_{13}, r_{23}, r_{14}, r_{24}, r_{34} \). It
is clear that in actual variational calculations only one spin function, e.g., the $\chi_1$ function, need be used. Another useful trick (so-called ‘doubling’) is based on the use of the same set of non-linear parameters in the two radial parts in Eq.\(\text{(2)}\).

In our earlier work [1] we have introduced an advanced set of radial basis functions for three-electron atomic calculations. In [1] this set was called the semi-exponential basis set. In general, the semi-exponential variational expansion of the radial function $\psi_{L=0}(A;\{r_{ij}\})$ is written in the form

$$\psi_{L=0}(A;\{r_{ij}\}) = \sum_{k=1}^{N} C_k r_{23}^{n_1(k)} r_{13}^{n_2(k)} r_{12}^{n_3(k)} r_{14}^{m_1(k)} r_{24}^{m_2(k)} r_{34}^{m_3(k)} \exp(-\alpha_k r_{14} - \beta_k r_{24} - \gamma_k r_{34})$$

(3)

where $\alpha_k, \beta_k, \gamma_k$ ($k = 1, 2, \ldots, N$) are the varied non-linear parameters. The presence of the varied non-linear parameters in Eq.\(\text{(3)}\) is the main and very important difference with the traditional Hylleraas variational expansion (see, e.g., [7]) for which in Eq.\(\text{(3)}\) we always have $\alpha_1 = \ldots = \alpha_N, \beta_1 = \ldots = \beta_N$ and $\gamma_1 = \ldots = \gamma_N$. Note that all matrix elements of the Hamiltonian, Eq.\(\text{(1)}\), and overlap matrix needed in computations with the use of the semi-exponential basis, Eq.\(\text{(3)}\), contain the same three-electron integrals which arise for the usual Hylleraas expansion (for more detail, see [1]). In other words, numerical calculation of all matrix elements with semi-exponential functions is no more difficult problem, than for the traditional Hylleraas radial functions. This also simplifies numerical computation of the bound state properties (i.e. expectation values) in the semi-exponential basis set. Our algorithms used in calculations of all required matrix elements is based on the Perkins formula for three-electron integrals [8] in relative coordinates. Note also that all calculations in this work have been performed with the use of standard quadruple precision accuracy (30 decimal digits per computer word).

In actual atomic systems any many-electron wave function must be completely antisymmetric upon all electron variables, i.e. upon all electron spatial and spin variables. For three-electron atomic wave function this requirement is written in the form $\hat{A}_{123} \Psi(1,2,3) = -\Psi(1,2,3)$, where $\Psi$ is given by Eq.\(\text{(2)}\) and $\hat{A}_e$ is the three-particle (= electron) antisymmetrizer $\hat{A}_e = \hat{e} - \hat{P}_{12} - \hat{P}_{13} - \hat{P}_{23} + \hat{P}_{123} + \hat{P}_{132}$. Here $\hat{e}$ is the identity permutation, while $\hat{P}_{ij}$ is the permutation of the $i$-th and $j$-th particles. Analogously, the operator $\hat{P}_{ijk}$ is the permutation of the $i$-th, $j$-th and $k$-th particles. In actual computations antisymmetrization of the total wave function is reduced to the proper antisymmetrization of corresponding matrix elements (for more detail, see, e.g., [1]). Each of these matrix ele-
ments is written in the form $\langle \Psi \mid \hat{O} \mid \Psi \rangle$, where $\hat{O}$ is an arbitrary spin-independent quantum operator which is truly symmetric upon all interparticle permutations. The wave function $\Psi$, Eq.(2), contains the two different radial parts $\psi$ and $\phi$. By performing the integration over all spin coordinates from here one finds the four spatial projectors $P_{\psi\psi}, P_{\psi\phi} = P_{\phi\psi}$, and $P_{\phi\phi}$ presented in [1]. In fact, the explicit form of the $P_{\psi\psi}$ and $P_{\phi\phi}$ projectors given in [1] must be corrected (there is an obvious misprint in the formulas given in [1]).

$$P_{\psi\phi} = \frac{1}{2} \left( \hat{P}_{13} - \hat{P}_{23} + \hat{P}_{123} - \hat{P}_{132} \right)$$

(4)

$$P_{\phi\psi} = \frac{1}{2} \left( \hat{P}_{13} - \hat{P}_{23} + \hat{P}_{123} - \hat{P}_{132} \right)$$

(5)

For an arbitrary truly symmetric spin-independent operator $\hat{O}$ each of these four projectors produces matrix elements $\langle \Psi \mid \hat{O} \mid \Psi \rangle$ of the correct permutation symmetry (for doublet states) between all three electrons. The explicit formulas for all matrix elements obtained with the radial basis functions, Eq.(3), and for three-electron integrals needed in calculations can be found in [1].

III. CALCULATIONS

Let us apply the semi-exponential variational expansion, Eq.(3), to numerical calculations of the ground $1^2S$-state in the three-electron $\infty Li$ atom. In this study we consider the two variational wave functions: (a) the wave function which contains 28 radial basis functions, Eq.(3), and (b) the wave function which includes 40 radial basis functions, Eq.(3). The results (in atomic units) obtained with these two trial wave functions can be found in Table I. Tables II and III contain the corresponding radial basis functions, Eq.(3), i.e. the powers $n_1(k), n_2(k), n_3(k), m_1(k), m_2(k), m_3(k)$ of six radial variables $r_{12}, r_{13}, r_{23}, r_{14}, r_{24}, r_{34}$ and optimized non-linear parameters $\alpha_k, \beta_k, \gamma_k$. As follows from Table I our variational energies obtained for the ground $1^2S$-state in the $\infty Li$ atom with the use of semi-exponential variational expansion, Eq.(2), are substantially lower than the corresponding energies determined for this state with the same Hylleraas wave function [7]. Note also that the non-linear parameters used in our method (in Eq.(3)) are constantly varied. Therefore, it is hard to say that the total energies obtained in some calculations are ‘final’. Formally, based on the known convergence rate(s) for our data and by using a few extrapolation procedures we can approximately evaluate the limits to which our variational energies will converge, if we
could perform an infinite number of variations for the non-linear parameters in Eq. (3). Such limits for the total energies are shown in the fourth column of Table I. These values indicate that, e.g., our 40-term variational wave function can produce, in principle, very accurate variational energies, if the optimization of non-linear parameters in Eq. (3) will continue.

In [7] Larsson proposed a simple (but useful!) trick which allows one to increase the overall accuracy of the trial (doublet) wave function. Later this trick was called ‘doubling’ of the wave function and it was used practically in all calculations of the bound doublet states in three-electron atomic systems. The idea of doubling is simple and transparent. If we already know the radial function constructed for one spin configuration, e.g., for \( \chi_1 = \alpha \beta \alpha - \beta \alpha \alpha \) from Eq. (2), then we can use exactly the same radial basis function for another spin configuration \( \chi_2 = 2\alpha \alpha \beta - \beta \alpha \alpha - \alpha \beta \alpha \). Formally, it doubles the total number of basis functions in the trial wave function. According to the variational principle the total variational energy can only decrease during such a procedure. The problem of linear dependence of basis functions is avoided in this procedure, since the two spin functions \( \chi_1 = \alpha \beta \alpha - \beta \alpha \alpha \) and \( \chi_2 = 2\alpha \alpha \beta - \beta \alpha \alpha - \alpha \beta \alpha \) are independent of each other. In fact, for Hylleraas variational expansion the ‘doubling’ does not work properly, since there are obvious linear dependencies between different radial basis functions in those cases when some non-linear parameters coincide with each other (for more detail, see [7]). In semi-exponential variational expansion Eq. (3) all optimized non-linear parameters are independent of each other. Therefore, the coincidence of the pre-exponential factors in Eq. (3) is not crucial and does not mean that such basis functions are linearly dependent. This drastically simplifies the actual ‘doubling’ for Eq. (3). The energies obtained with the use of ‘doubling’ of our variational wave functions can be found in the fifth column of Table I. It is clear that the non-linear parameters (or parameters in the exponents in Eq. (3)) from the second part of the total wave function are not optimal, i.e. for all terms which contain basis functions with numbers \( i \geq 41 \) the non-linear parameters are not optimal. These 120 (= 40 \( \times \) 3) non-linear parameters can be re-optimized and this drastically improves the overall quality of the total wave function. For instance, approximate re-optimization of the last 40 non-linear parameters in the wave function gives the ground state energy -7.4780583419 a.u., which is much better than the ‘doubling’ energy (-7.4780581691 a.u.) from Table I. Note also that our value of the total energy of the ground state in the Li atom is better than the total energy obtained in [10] with the use of 352 basis functions.
As follows from Table I the doubling is not an effective approach for our trial wave functions with the carefully optimized non-linear parameters. However, we can modify the original idea of doubling into something new which is substantially more effective in actual computations. To illustrate one of such modifications, let us assume that we have constructed a 40-term variational wave function, Eq. (3) which contains \(40 \times 3 = 120\) carefully optimized non-linear parameters \(\alpha_1, \beta_1, \gamma_1, \ldots, \alpha_{40}, \beta_{40}, \gamma_{40}\). At the second step of our procedure we can add forty additional basis functions with the same pre-exponential factors \(r_{23}^{n_1(k)} r_{12}^{n_2(k)} r_{14}^{n_3(k)} r_{24}^{m_1(k)} r_{34}^{m_2(k)} r_{34}^{m_3(k)}\), but slightly different exponents in Eq. (3). In reality, these new exponents have been chosen quasi-randomly from three different intervals, e.g.,

\[
\alpha_{i+40} = \alpha_i + 0.0057 \cdot \langle \langle \frac{i(i+1)\sqrt{2}}{2} \rangle \rangle
\]

\[
\beta_{i+40} = \beta_i + 0.0063 \cdot \langle \langle \frac{i(i+1)\sqrt{3}}{2} \rangle \rangle
\]

\[
\gamma_{i+40} = \gamma_i + 0.0049 \cdot \langle \langle \frac{i(i+1)\sqrt{5}}{2} \rangle \rangle
\]

where \(i = 1, 2, \ldots, 40\) and \(\langle \langle x \rangle \rangle\) designates the fractional part of the real number \(x\). Small deviations of these new exponents from the known ‘optimal’ values (i.e. from \(\alpha_i, \beta_i, \gamma_i\), where \(1 \leq i \leq 40\)) produce the extended wave function of ‘almost optimal’ quality. On the other hand, even these small differences between exponents allows one to avoid a linear dependence between basis vectors in Eq. (3). Obviously, this procedure can be repeated a number of times. This allows one to construct very accurate trial wave functions which contain not only 80, but 400, 800 and even 2000 basis functions with almost ‘optimal’ non-linear parameters.

It is very interesting to perform variational calculations of the ground state of the \(\infty Li\) atom with the use of 60-term wave function constructed from the analogous 60-term wave Larsson’s wave function [7]. The variational total energy obtained in [7] with that wave function and one spin function \(\chi_1\) was \(-7.4780103597\) a.u. Our 60-term trial wave function with one spin function \(\chi_1\) constructed in [1] from the same radial basis functions corresponds to the substantially lower total energy \(E = -7.478057561\) a.u. The current total energy is \(-7.4780597045\) a.u. (only one spin function \(\chi_1\) is used in our calculations). Note that our current total energy rapidly decreases with almost constant rate \(\approx 0.5 \cdot 10^{-7}\) a.u. per optimization cycle, i.e. per one variation of all 180 (= \(60 \times 3\)) non-linear parameters in the trial wave function. This total energy is better than the values obtained in [11] with
the use of 503 Hylleraas basis functions (selected radial configurations were used in such calculations). Moreover, this total energy is slightly better than the value obtained in [12].

The doubling of our 60-term wave function produces the total energy $-7.4780597761$ a.u. This energy is close to the known ‘exact’ answer $-7.478060323904$ a.u. [9]. We expect that after an infinite number of variations of the non-linear parameters the total energy of the $\infty$Li atom obtained with our 60-term radial function and one spin function will converge to the value $-7.4780603(3)$ a.u. which is very close to the actual ground state energy. It will be an outstanding result to obtain the value lower than $-7.4780602$ a.u. for the total energy of the ground $1^2S$–state in the $\infty$Li atom by using only 60-term variational wave function.

IV. DISCUSSIONS AND CONCLUSION

The semi-exponential variational expansion [1] is applied for bound state calculations of three-electron atomic systems. It is shown that this variational expansion allows one to construct compact and accurate variational wave functions for three-electron atomic systems. Currently, the use of semi-exponential radial basis functions is the best way to produce compact and accurate wave functions for three-electron atomic systems. The total energies obtained in this study for the ground $1^2S$-state of the $\infty$Li atom are more accurate than our earlier results from [1] and substantially more accurate than the original Larsson’s wave function [7] with the same number of terms.

The results indicate clearly that our semi-exponential variational expansion, Eq. (3), has a substantially greater potential for variational bound state calculations in three-electron atomic systems than we have anticipated originally [1]. Currently, we continue the process of numerical optimization of the non-linear parameters in our trial wave functions constructed with the use of semi-exponential variational expansions. Note that the choice of Larsson’s wave function(s) as the first approximation to the semi-exponential variational expansion is not crucial for our method. Many other choices are also possible. For instance, our next step will be re-optimization of the non-linear parameters in the 352-term wave function used in [10]. It will take some time, but with such a wave function we hope to produce the total energy which is close to the known ‘exact’ energy for the ground state of the $\infty$Li atom ($E = -7.478060323904$ a.u.).

When our research of the semi-exponential variational expansion started we could not
expect such impressive results. Currently, the variational wave functions constructed with
the use of semi-exponential variational expansion are of great interest for many scientific
problems which include the Li atom and other atomic and quasi-atomic three-electron sys-
tems. In particular, we have made numerous improvements in our original computer code
[1]. Our next goal is to generalize the semi-exponential basis to the four-electron atomic
problems. The semi-exponential variational expansion for four-electron atomic systems can
be used to obtain compact and accurate wave functions of the ground singlet $1^1S$–state and
triplet $2^3S$–states of the Be atom and Be-like ions. It is clear that our method can also be
used for rotationally excited states in atomic systems, i.e. for states with $L \geq 1$, where $L$ is
the electron angular momentum.

In conclusion, it should be mentioned that numerous attempts to improve the overall
quality of radial basis functions for three-electron atomic systems (in general, for four-
bond Coulomb systems) started almost 20 years ago (see, e.g., [14], [15], [16]). In part, it
was a reaction to low efficiency of the traditional Hylleraas variational expansion for such
systems. Indeed, the total number of terms in modern versions of Hylleraas variational
expansions already exceeded 13,000 and still growing. For the Li atom (ground state) such
wave functions allows one to determine 12 - 13 stable decimal digits in the total energy.
Comparison of a large number of numerical results for the ground state of the lithium atom
can be found in Table II from [13]. The new Hylleraas wave function with 65,000 terms
will allow one to obtain $\approx 15$ stable decimal digits in the total energy. It is clear that
such a method cannot be considered as a reasonable and appropriate approach for accurate
variational computations of the bound states in four-body systems.

An alternative approach for construction of highly accurate four-body wave functions was
proposed in [14], [15], [16]. It is based on the closed analytical formulas derived in [17] for
the basic four-body integral. As it follows from actual calculations this method allows one
to obtain very accurate bound state energies essentially for all Coulomb four-body systems,
including $\infty$Li atom ($E = -7.47806025114$ a.u., 50 radial basis functions (exponents) with
the spin function $\chi_1$ plus 19 radial basis functions with the spin function $\chi_2$ (their definitions are
given above), bi-positronium Ps$_2$ ($E = -0.51600377267$ a.u., 50 exponential basis functions)
and $\infty$HPs ($E = -0.78914861151$ a.u., 50 exponential basis functions). Very good values
for the total (bound) state energies have also been obtained for the $pp\mu\mu$ and $dd\mu\mu$ four-
body bi-muon systems. These total energies can be improved even further by using more
careful optimization of the non-linear parameters in the trial wave functions. For accurate computations of the H$_2$ molecule and other similar (molecular) systems the method [15] must be modified to include the complex values for some non-linear parameters (as was done in [16]).

Note, however, that relations between these variational expansions based on the formula from [17] and traditional Hylleraas variational expansion are extremely complicated. Further analysis shows that the source of these difficulties is directly related with the fundamental properties of the four-body perimetric coordinates [18], rather than with the lack of ‘good representations’ for the formula Eqs.(2.1) - (2.9) from [17]. As follows from the properties of the four-body perimetric coordinates [18] it is very hard to represent any of these compact and accurate ‘exponential’ wave functions in terms of the Hylleraas basis functions. The overall complexity of problems arising here is comparable with the difficulties which can be found in the original problem. Many advantages of the ‘exponential’ wave functions, e.g., their very accuracy, can be lost during this procedure. In many cases, it is simpler to re-calculate the corresponding energies from the very beginning by using the traditional Hylleraas variational expansion. This is the main reason why we do not want to discuss here some recent developments in the four-body exponential and related variational expansions (see, e.g., [19]).

Our approach allows one to produce compact and accurate wave functions which are easily related with the Hylleraas basis set of radial functions. This means that all such compact and accurate wave functions can directly be used in computations of various bound state properties and transition probabilities. The second advantage of the semi-exponential variational expansion follows from relatively simple formulas for all matrix elements needed in highly accurate computations and optimization processes.

TABLE II: An example of the trial wave function constructed with the use of $N = 28$ semi-exponential radial basis functions. This wave function produces the total energy $E = -7.4780363801$ a.u. for the ground $1^2S$–state of the $\infty Li$ atom. Only one electron spin-function $\chi_1 = \alpha \beta \alpha - \beta \alpha \alpha$ was used in these calculations.

| $N$ | $n_1$ | $n_2$ | $n_3$ | $m_1$ | $m_2$ | $m_3$ | $\alpha$ | $\beta$ | $\gamma$ |
