VALUATION AND HEDGING OF OTC CONTRACTS
WITH FUNDING COSTS, COLLATERALIZATION
AND COUNTERPARTY CREDIT RISK: PART 1

Abstract
The research presented in this work is motivated by recent papers by Brigo et al. [9,10,11], Crépey [12,13], Burgard and Kjær [3], Fujii and Takahashi [16], Piterbarg [29] and Pallavicini et al. [28]. Our goal is to provide a sound theoretical underpinning for some results presented in these papers by developing a unified martingale framework for the non-linear approach to hedging and pricing of OTC financial contracts. The impact that various funding bases and margin covenants exert on the values and hedging strategies for OTC contracts is examined. The relationships between our research and papers by other authors, with an exception of Piterbarg [29] and Pallavicini et al. [28], are not discussed in this Part 1 of our research. More detailed studies of these relationships and modeling issues are examined in the follow-up Part 2.

†The research of Marek Rutkowski was supported under Australian Research Council’s Discovery Projects funding scheme (DP120100895).

1 Introduction

The aim of our research is to build a framework for valuation and hedging of OTC contracts between two (or, in perspective, more than two) defaultable counterparties in the presence of funding costs, collateralization and netting. In the first part of the paper, the goal is to derive general results for wealth dynamics of trading strategies in a market model where funding costs are specific to each party. In addition, we cover the issues of benefits and losses at default, netting of positions, and various covenants regarding the margin account in the case of collateralized contracts. We thus hope to develop a fairly general framework, which can be applied to a wide range of models and problems arising in practice. In the second part of the paper, we will apply our general results to problems arising in the market practice, specifically, to valuation of contracts under different funding costs for the defaultable counterparties. Following the existing terminological convention, the valuation problem is abbreviated henceforth as FCVA (funding and credit valuation adjustment), although it is reasonable to argue that we simply deal here with the fair valuation of a contract under specific, sometimes quite complicated, trading rules. The commonly used term ‘adjustment’ refers to a comparison of solutions to the valuation problem obtained using at least two different set-ups, and this is not necessarily our goal. We would thus like to stress that our approach should be contrasted with the heuristic ‘additive adjustments approach’, which hinges on the additive price decomposition

\[ \hat{\pi} = \pi + \text{CVA} + \text{DVA} + \text{FVA} + \text{additional adjustments (if needed)} \] (1.1)

where \( \pi \) is the fair value of the uncollateralized contract between non-defaultable counterparties and \( \hat{\pi} \) is the ‘value’ for the investor of the contract between two defaultable parties with idiosyncratic funding costs, collateral, and other relevant costs and/or risks. In most existing papers, the authors attempted to obtain explicit representation for the price decomposition (1.1) using three tools:
(a) a thorough analysis of the contract’s future cash flows,
(b) some (rather arbitrary) choice of discounting of futures cash flows, and
(c) the postulate that the risk-neutral valuation can be applied, so that the price is computed as the (conditional) expectation of discounted cash flows.

It is still uncommon in this area to directly refer to hedging arguments, although this technique is used in some recent works. A simple decomposition of a contract into a sequence of cash flows is justified when one deals with a contract in which cash flows themselves are independent of hedging strategies or, equivalently, the yet unknown value process of the contract. This postulate is manifestly wrong when one deals with a collateralized contract, in which the collateral amount is given in terms of the ‘fair’ (or market) value of the contract. By the same token, a particular form of discounting was usually adopted as a plausible postulate, rather than derived as a strict result starting from some fundamental arguments. Obviously, any ad hoc choice of discounting is questionable. Therefore, the practical approach summarized briefly above is manifestly flawed on numerous counts, though it may still sometimes yield a correct answer, provided that the problem is simple enough, so that a sensible solution is readily available anyway to a skilled quant. First, discounting using risk-free rate is reasonable only when the risk-free bond is traded. Otherwise, when multiple yield curves are present, the choice of a discount factor is not arbitrary and thus this issue needs to be carefully addressed. Second, risk-neutral valuation is justified only when the wealth process of a hedging strategy is a martingale under some probability measure after suitable discounting, so that the analysis of the drift term in the wealth dynamics is another crucial step and it can only be done by considering first trading strategies for both counterparties. In addition, it is well known that in the case of a non-linear pricing rule (or, equivalently, a solution to a non-linear backward stochastic differential equation (BSDE)), the discounted wealth process is not a martingale, so the classic approach to arbitrage pricing does not apply. Third, although the choice of a numéraire asset is in principle arbitrary, the choice of the discount factor should be consistent with the actual dynamics of the wealth under the statistical probability measure. Even when one insists on the choice of a conventional ‘risk-free rate’ as a discount factor, the problem of finding the wealth dynamics under the corresponding martingale measure remains a crucial issue that need to be analyzed in detail. As already mentioned, the wealth dynamics will usually depend on the choice of a hedging strategy and thus instead of computing the conditional expectation, one needs to solve a non-linear BSDE.
2 Trading Strategies and Wealth Dynamics

A finite trading horizon \( T \) for our model of the financial market is fixed throughout the paper. All processes introduced in what follows are implicitly assumed to be given on the underlying probability space \((\Omega, \mathcal{G}, \mathbb{G}, \mathbb{P})\) where the filtration \( \mathbb{G} = (\mathcal{G}_t)_{t \in [0,T]} \) models the flow of information available to all traders. We denote by \( S^i \) the \textit{ex-dividend price} (or simply the \textit{price}) of the \( i \)th risky security with the cumulative dividend stream after time 0 represented by the process \( A^i \). Let \( B^i \) stand for the corresponding \textit{funding account} representing either unsecured or secured funding for the \( i \)th asset. A more detailed financial interpretation of these accounts will be discussed later. We also introduce the \textit{cash account} \( B^0 \), which is used for unsecured lending or borrowing of cash. In the case when the borrowing and lending cash rates are different, we will use symbols \( B^{0,+} \) and \( B^{0,-} \) to denote the processes modeling unsecured lending and borrowing cash accounts, respectively. A similar convention will be applied to processes \( B^{i,+} \) and \( B^{i,-} \). For any random variable \( \chi \), the equality \( \chi = \chi^+ - \chi^- \) is the usual decomposition of a random variable \( \chi \) into its positive and negative parts. Note, however, that this convention does not apply to double indices, such as \( 0^+ \) or \( 0^- \).

**Assumption 2.1** We assume that:

(i) \( S^i \) for \( i = 1, 2, \ldots, d \) are càdlàg semimartingales,
(ii) \( A^i \) for \( i = 1, 2, \ldots, d \) are càdlàg processes of finite variation with \( A^i_0 = 0 \),
(iii) \( B^j \) for \( j = 0, 1, \ldots, d \) are strictly positive and continuous processes of finite variation with \( B^j_0 = 1 \).

The \textit{cumulative-dividend price} \( S^{i,\text{cld}} \) is given as

\[
S^{i,\text{cld}}_t := S^i_t + B^i_t \int_{(0,t]} (B^i_u)^{-1} dA^i_u, \quad t \in [0,T],
\]

and thus the \textit{discounted cumulative-dividend price} \( \hat{S}^{i,\text{cld}} := (B^i)^{-1} S^{i,\text{cld}} \) satisfies

\[
\hat{S}^{i,\text{cld}}_t = \hat{S}^i_t + \int_{(0,t]} (B^i_u)^{-1} dA^i_u, \quad t \in [0,T],
\]

where we denote \( \hat{S}^i := (B^i)^{-1} S^i \). If the \( i \)th traded asset does not pay any dividend up to time \( T \) then the equality \( S^{i,\text{cld}}_t = S^i_t \) holds for every \( t \in [0,T] \). Note that the processes \( S^{i,\text{cld}} \), and thus also the processes \( \hat{S}^{i,\text{cld}} \), are càdlàg.

Note that formula (2.1) hinges on an implicit assumption that positive (resp. negative) dividends from the \( i \)th asset are invested in (resp. funded from) the \( i \)th funding account \( B^i \). Since the main valuation and hedging results for derivative securities obtained in this section are represented in terms of primitive processes \( S^i, B^i \) and \( A^i \), rather than \( S^{i,\text{cld}} \), our choice of a particular convention regarding reinvestment of dividends associated with the asset \( S^i \) is immaterial.

## 2.1 Trading Strategies and Funding Costs

We are in a position to introduce trading strategies based on a family of traded assets introduced above. In this preliminary section, we mainly focus on definitions and notation used in what follows.

**Assumption 2.2** We assume that \( \xi^i \) for \( i = 1, 2, \ldots, d \) (resp. \( \psi^j \) for \( j = 0, 1, \ldots, d \)) are arbitrary \( \mathbb{G} \)-predictable (resp. \( \mathbb{G} \)-adapted) processes such that the stochastic integrals used in what follows are well defined.

In Sections 2.1 and 2.2 we consider a dynamic portfolio \( \varphi = (\xi, \psi) = (\xi^1, \ldots, \xi^d, \psi^0, \ldots, \psi^d) \) composed of risky securities \( S^i, i = 1, 2, \ldots, d \), the cash account \( B^0 \) used for unsecured lending/borrowing, and funding accounts \( B^i, i = 1, 2, \ldots, d \), used for (unsecured or secured) funding of the \( i \)th asset. In addition, we introduce a càdlàg process \( A \) of finite variation, with \( A_0 = 0 \), which is aimed to represent the \textit{external cash flows}, that is, the cash flows associated with some OTC contract.
Remark 2.1 In the financial interpretation, the process $A$ is aimed to model all contractual cash flows either paid out from the wealth or added to the wealth, as seen from the perspective of the hedger (the other party is referred to as the counterparty). The name contractual cash flows is used to emphasize that the process $A$ will typically model all cash flows directly generated by a security to be replicated by means of a trading strategy $\varphi$.

The wealth of a trading strategy depends on both $\varphi$ and $A$, as is apparent from the next definition. It is important to stress that hedging strategy $\varphi$ and external cash flows $A$ cannot be separated, in general, since the wealth will depend in a non-linear way on both $\varphi$ in $A$, in general.

Definition 2.1 We say that a trading strategy $(\varphi, A)$ with cash flows $A$ is self-financing whenever the wealth process $V(\varphi, A)$, which is given by the formula

$$V_t(\varphi, A) := \sum_{i=1}^{d} \xi^i_t S^i_t + \sum_{j=0}^{d} \psi^j_t B^j_t,$$  

(2.3)

satisfies, for every $t \in [0, T]$,

$$V_t(\varphi, A) = V_0(\varphi, A) + \sum_{i=1}^{d} \int_{(0,t]} \xi^i_u d(S^i_u + A^i_u) + \sum_{j=0}^{d} \int_{(0,t]} \psi^j_u dB^j_u + A_t$$  

(2.4)

where $V_0(\varphi, A)$ is an arbitrary real number.

Remark 2.2 Observe that (2.4) yields the following wealth decomposition

$$V_t(\varphi, A) = V_0(\varphi, A) + G_t(\varphi, A) + F_t(\varphi, A) + A_t$$  

(2.5)

where

$$G_t(\varphi, A) := \sum_{i=1}^{d} \int_{(0,t]} \xi^i_u (dS^i_u + dA^i_u)$$  

(2.6)

represents the gains (or losses) associated with holding long/short positions in risky assets $S^1, \ldots, S^d$ and

$$F_t(\varphi, A) := \sum_{j=0}^{d} \int_{(0,t]} \psi^j_u dB^j_u$$  

(2.7)

represents the portfolio’s funding costs. Such a simple additive decomposition of the wealth process will no longer hold when more constraints will be imposed on trading.

Remark 2.3 Sometimes (see, e.g., [29]), the process $\gamma$, which is given by

$$\gamma_t = V_0(\varphi, A) + F_t(\varphi, A) + \sum_{i=1}^{d} \int_{(0,t]} \xi^i_u dA^i_u + A_t$$

for $t \in [0, T]$, is referred to as the cash process financing the portfolio $\varphi$. In this context, it is important to stress that the equality

$$V_t(\varphi, A) = \sum_{i=1}^{d} \int_{(0,t]} \xi^i_u dS^i_u + \gamma_t,$$

holds but, in general, we have that

$$V_t(\varphi, A) \neq \sum_{i=1}^{d} \xi^i_t S^i_t + \gamma_t.$$
2.2 Elementary Market Model

By the elementary market model we mean a preliminary framework in which trading in funding accounts \(B^i\) and risky assets \(S^i\) is unconstrained. This is indeed a fairly simplistic set-up, so its analysis should merely be seen as a first step towards more realistic models with trading constraints. We will argue that explicit formulae for the wealth dynamics under various kinds of trading constraints can be obtained from the basic result, Proposition 2.1, by refining the computations involving the wealth process and funding costs.

Let \(V^{\text{cld}}(\varphi, A)\) be the netted wealth of a trading strategy \((\varphi, A)\), as given by the following equality

\[
V_t^{\text{cld}}(\varphi, A) := V_t(\varphi, A) - B^0_t \int_{(0,t]} \left(B^0_u \right)^{-1} dA_u. \tag{2.8}
\]

It is worth noting that the netted wealth \(V^{\text{cld}}(\varphi, A)\) is a useful theoretical construct, rather than a practical concept. On the one hand, the cash flows stream \(A\) is included in the wealth \(V(\varphi, A)\); on the other hand, the same cash flows stream is formally reinvested in \(B^0\) and subtracted from \(V(\varphi, A)\). We will argue that the discounted netted wealth given by \(2\.8\) (or some extension of this formula) will be a convenient tool to examine arbitrage-free property for trading under funding and collateralization.

Remark 2.4 Obviously, the wealth process depends on a strategy \(\varphi\) and contractual cash flows \(A\), so that notation \(V(\varphi, A)\) makes perfect sense. However, for the sake of brevity, the shorthand notation \(V(\varphi)\) is used in the remaining part of Section 2.1.

We introduce the following notation

\[
K_t^i := \int_{(0,t]} B^0_u d\hat{S}^i_u + A_t^i = \int_{(0,t]} B^0_u d\hat{S}^{i,\text{cld}}_u \tag{2.9}
\]

and

\[
K_t^\varphi := \int_{(0,t]} B^0_u d\tilde{V}_u(\varphi) - A_t = \int_{(0,t]} B^0_u d\tilde{V}^{\text{cld}}(\varphi) \tag{2.10}
\]

where we set \(\tilde{V}^{\text{cld}}(\varphi) := (B^0)^{-1}V^{\text{cld}}(\varphi)\) and \(\tilde{V}(\varphi) := (B^0)^{-1}V(\varphi)\). Obviously,

\[
\tilde{V}_t^{\text{cld}}(\varphi) = V_0(\varphi) + \int_{(0,t]} (B^0_u)^{-1} dK_u^\varphi. \tag{2.11}
\]

Remark 2.5 The process \(K^i\) is equal to the wealth, discounted by the funding account \(B^i\), of a self-financing strategy in risky security \(S^i\) and the associated funding account \(B^i\) in which \(B^i\) units of the cumulative-dividend price of the \(i\)th asset is held at time \(t\).

The following proposition is fairly abstract and is primarily tailored to cover the valuation and hedging of an unsecured financial derivative. We thus mainly focus here on funding costs associated with trading in risky assets. A study of secured (that is, collateralized) contracts is postponed to the next section. We will argue later on that this result is a good starting point to analyze a wide spectrum of practically appealing situations (see, in particular, Propositions 2.2, 2.3 and 2.4). To achieve our goals, it will be enough to impose specific constraints on trading strategies, which will reflect particular market conditions faced by the hedger (such as different lending, borrowing and funding rates) and/or covenants of a contract under study (such as a collateral or close-out payoffs or benefits stemming from defaults).

Proposition 2.1 (i) For any self-financing strategy \(\varphi\) we have that for every \(t \in [0,T]\)

\[
K_t^\varphi = \sum_{i=1}^d \int_{(0,t]} \xi_u^i dK_u^i + \sum_{i=1}^d \int_{(0,t]} (\psi_u^i B^i_u + \xi_u^i S^i_u)(\bar{B}^i_u)^{-1} d\bar{B}^i_u. \tag{2.12}
\]
where we set $\tilde{B}^i := (B^0)^{-1}B^i$.

(ii) The equality

$$K_t^\varphi = \sum_{i=1}^d \int_{(0,t]} \xi_i^o \, dK_u^i, \quad t \in [0,T],$$

holds if and only if

$$\sum_{i=1}^d \int_{(0,t]} (\psi_i^o B_u^i + \xi_i^o S_u^i) (\tilde{B}_u^i)^{-1} \, d\tilde{B}_u^i = 0, \quad t \in [0,T].$$

(iii) In particular, if for each $i = 1,2,\ldots,d$ we have that: either $B^i_t = B^0_t$ for all $t \in [0,T]$ or

$$\psi_i^o B_t^i + \xi_i^o S_t^i = 0, \quad t \in [0,T],$$

then (2.14) is valid and thus (2.13) holds.

(iv) Assume that $B^i = B^0$ for every $i = 1,2,\ldots,d$ and denote $\tilde{S}^{i,cld} = (B^0)^{-1}S^{i,cld}$. Then

$$d\tilde{V}^{cld}(\varphi) = \sum_{i=1}^d \xi_i^o \, d\tilde{S}^{i,cld}.$$  

Proof. Recall that (see (2.14))

$$dV_t(\varphi) = \sum_{i=1}^d \xi_i^o \, d(S^i_t + A^i_t) + \sum_{j=0}^d \psi^i_j \, dB^i_j + dA_t.$$  

Using (2.13), for the discounted wealth $\tilde{V}(\varphi) = (B^0)^{-1}V(\varphi)$ we obtain

$$d\tilde{V}(\varphi) = \sum_{i=1}^d \xi_i^o \, d((B^0)^{-1}S^i_t) + \sum_{i=1}^d \xi_i^o ((B^0)^{-1})^{-1} \, dA^i_t + \sum_{i=1}^d \psi^i_j \, d((B^0)^{-1}B^i_t) + (B^0)^{-1} \, dA_t$$

$$= \sum_{i=1}^d \xi_i^o \, d\tilde{S}^{i,cld} + \sum_{i=1}^d \psi^i_j \, dB^i_t + (B^0)^{-1} \, dA_t$$

where $\tilde{B}^i = (B^0)^{-1}B^i$ and

$$\tilde{S}^{i,cld} = S^i_t(B^0)^{-1} + \int_{(0,t]} (B^0_u)^{-1} \, dA_u^i = \tilde{S}^i_t + \int_{(0,t]} (B^0_u)^{-1} \, dA_u^i.$$  

Consequently,

$$dK_t^\varphi = B^0_t \, d\tilde{V}(\varphi) - dA_t = \sum_{i=1}^d B^0_t \xi_i^o \, d\tilde{S}^{i,cld} + \sum_{i=1}^d B^0_t \psi^i_j \, dB^i_t$$

$$= \sum_{i=1}^d B^0_t \xi_i^o \, d(\tilde{S}^i_t - \tilde{B}^i_t) + \sum_{i=1}^d B^0_t \xi_i^o \, ((B^0)^{-1})^{-1} \, dA^i_t + \sum_{i=1}^d B^0_t \psi^i_j \, dB^i_t$$

$$= \sum_{i=1}^d B^0_t \xi_i^o \, d\tilde{B}^i_t + \sum_{i=1}^d \xi_i^o \, dB_t^i + \sum_{i=1}^d \psi^i_j \, dB^i_t$$

$$= \sum_{i=1}^d B^0_t \xi_i^o \, d\tilde{B}^i_t + \sum_{i=1}^d \xi_i^o \, dB_t^i + \sum_{i=1}^d \psi^i_j \, dB^i_t.$$
This completes the proof of part (i). Parts (ii) and (iii) now follow easily. By combining formulae (2.9) and (2.12), we obtain part (iv). Note that (2.16) is the classic condition for a market with a single savings account $B^0$. 

**Remark 2.6** Note that equality $B^i = B^0$ (resp. equality (2.15)) corresponds to unsecured (resp. secured) funding of the $i$th asset (unsecured funding means that a risky security is not posted as collateral). In the financial interpretation, condition (2.15) means that at any date $t$ the value of the long or short position in the $i$th risky security should be exactly offset by the value of the $i$th secured funding account. Although this condition is aimed to cover the case of the fully secured funding of the $i$th risky asset using the corresponding repo rate, it is fair to acknowledge that it is rather restrictive and thus not always not practical. It is suitable for repo contracts with the daily resettlement, but it does not cover the case of long term repo contracts.

Note also that if condition (2.15) holds for all $i = 1, 2, \ldots, d$ then the wealth of a portfolio $\varphi$ satisfies $V_t(\varphi) = \psi_0 B^0$ for every $t \in [0, T]$. This is consistent with the interpretation that all gains/losses are immediately invested in the savings account $B^0$. To make this set-up more realistic, we need, in particular, to introduce different borrowing and lending rates and add more constraints on trading.

**Remark 2.7** More generally, the $i$th risky security can be funded in part using $B^i$ and using $B^0$ for another part, so that condition (2.15) may fail to hold. However, this case can also be covered by the model in which condition (2.15) is met by artificially splitting the $i$th asset into two 'sub-assets' that are subject different funding rules. Needless to say that the valuation and hedging results for a derivative security will depend on the way in which risky assets used for hedging are funded.

### 2.2.1 The Dynamics of the Wealth Process

To obtain more explicit representations for the wealth dynamics, we first prove an auxiliary lemma. From equality (2.17), one can deduce that the increment $dK^i$ represents the change in the price of the $i$th asset net of funding cost. For the lack of the better terminology, we propose to call $K^i$ the *netted realized cash flow* of the $i$th asset.

**Lemma 2.1** The following equalities hold, for all $t \in [0, T]$,

$$K^i_t = S^i_t - S^i_0 + A^i_t - \int_{(0,t]} S^i_u \, dB^i_u$$

(2.17)

and

$$K^\varphi_t = V_t(\varphi) - V_0(\varphi) - A_t - \int_{(0,t]} V_u(\varphi) \, dB^0_u.$$  

(2.18)

**Proof.** The Itô formula, (2.2) and (2.9) yield

$$\int_{(0,t]} B^i_u \, d\tilde{S}^{\text{cld}}_u = \int_{(0,t]} B^i_u \, dS^i_u + A^i_t = B^i_t \tilde{S}^i_t - B^i_0 \tilde{S}^i_0 - \int_{(0,t]} \tilde{S}^i_u \, dB^i_u + A^i_t$$

(2.19)

$$= S^i_t - S^i_0 + A^i_t - \int_{(0,t]} \tilde{S}^i_u \, dB^i_u.$$  

The proof of the second formula is analogous. \qed

In view of Lemma 2.1 the following corollary to Proposition 2.1 is immediate.
Corollary 2.1 Formula (2.12) is equivalent to the following expressions

\[
d\tilde{V}_t^{\text{cld}}(\varphi) = \sum_{i=1}^{d} \xi_i^i d\tilde{S}_t^{i,\text{cld}} + \sum_{i=1}^{d} \zeta_i^i (B_t^i)^{-1} d\tilde{B}_t^i, \tag{2.20}
\]

\[
dV_t(\varphi) = \tilde{V}_t(\varphi) dB_t^0 + \sum_{i=1}^{d} \xi_i^i dB_t^i + \sum_{i=1}^{d} \zeta_i^i (B_t^i)^{-1} d\tilde{B}_t^i + dA_t, \tag{2.21}
\]

\[
dV_t(\varphi) = \tilde{V}_t(\varphi) dB_t^0 + \sum_{i=1}^{d} \xi_i^i dB_t^i + \sum_{i=1}^{d} \zeta_i^i (\tilde{B}_t^i)^{-1} d\tilde{B}_t^i + dA_t \tag{2.22}
\]

where \(\zeta_i^i := \psi_i^i B_t^i + \xi_i^i S_t^i\). Hence the funding costs of \(\varphi\) satisfy

\[
F_t(\varphi) = \int_{(0,t]} \tilde{V}_u(\varphi) dB_u^0 + \int_{(0,t]} \sum_{i=1}^{d} \xi_i^i (\tilde{B}_u^i)^{-1} d\tilde{B}_u^i - \sum_{i=1}^{d} \int_{(0,t]} \xi_i^i S_u dB_u^i. \tag{2.23}
\]

Since the funding costs depend, in particular, on funding accounts \(B^0, \ldots, B^d\), we will sometimes emphasize this dependence by writing \(F(\varphi) = F(\varphi; B^0, \ldots, B^d)\).

Example 2.1 Suppose that the processes \(B^j, j = 0, 1, \ldots, d\) are absolutely continuous, so that they can be represented as \(dB_t^j = r_t^j B_t^j dt\) for some \(\mathbb{G}\)-adapted processes \(r^j, j = 0, 1, \ldots, d\). Then (2.21) yields

\[
dV_t(\varphi) = r_t^0 V_t(\varphi) dt + \sum_{i=1}^{d} \zeta_i^i (r_t^i - r_t^0) dt + \sum_{i=1}^{d} \xi_i^i (S_t^i - r_t^i S_t^0) dt + dA_t. \tag{2.24}
\]

The last formula implies that

\[
dV_t(\varphi) = \sum_{j=0}^{d} r_t^j \psi_t^j B_t^j dt + \sum_{i=1}^{d} \xi_i^i (S_t^i + dA_t^i) + dA_t, \tag{2.25}
\]

which can also be seen as an immediate consequence of (2.4). In particular, the dynamics of funding costs of \(\varphi\) are given by

\[
dF_t(\varphi) = \sum_{j=0}^{d} r_t^j \tilde{\psi}_t^j B_t^j dt. \tag{2.26}
\]

2.2.2 Common Unsecured Account

In the remaining part of this section, we will examine the consequences of our general results for various cases of practical interest. We first assume that \(B^i = B^0\) for \(i = 1, 2, \ldots, k\) for some \(k \leq d\). This means that all unsecured accounts \(B^1, \ldots, B^k\) fold down into a single cash account, denoted as \(B^0\), but secured accounts \(B^{k+1}, \ldots, B^d\) corresponding to repo rates may vary from one asset to another. Formally, it is now convenient to postulate that \(\psi^i = 0\) for \(i = 1, 2, \ldots, k\) so that a portfolio \(\varphi\) may be represented as \(\varphi = (\xi^1, \ldots, \xi^d, \psi^0, \psi^{k+1}, \ldots, \psi^d)\). Hence formula (2.3) reduces to

\[
V_t(\varphi) = \sum_{i=1}^{d} \xi_i^i S_t^i + \sum_{i=k+1}^{d} \psi_i^i B_t^i + \psi_t^0 B_t^0
\]

and the self-financing condition (2.4) becomes

\[
V_t(\varphi) = V_0(\varphi) + \sum_{i=1}^{d} \int_{(0,t]} \xi_i^i d(S_u^i + A_u^i) + \int_{(0,t]} \psi_t^0 dB_u^0 + \sum_{i=k+1}^{d} \int_{(0,t]} \psi_t^i dB_u^i + A_t.
\]
Consequently, equality (2.21) takes the following form

\[dV_t(\varphi) = \tilde{V}_t(\varphi) dB^0_t + \sum_{i=1}^k \xi^i_t B^0_t \, d\tilde{S}^{i,\text{cl}}_t + \sum_{i=k+1}^d \xi^i_t B^1_t \, d\tilde{S}^{i,\text{cl}}_t + \sum_{i=k+1}^d \zeta^i_t (\tilde{B}^1_t)^{-1} dB^1_t + dA_t \quad (2.27)\]

where we denote

\[\tilde{S}^{i,\text{cl}}_t := \tilde{S}^i_t + \int_{(0,t]} (B^0_u)^{-1} dA_u, \quad t \in [0,T],\]

where in turn \(\tilde{S}^i_t := (B^0)^{-1} S^i_t\).

**Example 2.2** If all accounts \(B^j, j = 0,1, \ldots, d\) are absolutely continuous so that, in particular, \(r^i = r^0\) for \(i = 1, 2, \ldots, k\), then

\[dV_t(\varphi) = \left( r^0_t \psi^0_t B^0_t + \sum_{i=k+1}^d r^i_t \psi^i_t B^i_t \right) dt + \sum_{i=1}^d \xi^i_t (dS^i_t + dA^i_t) + dA_t. \quad (2.28)\]

If, in addition, \(\zeta^i_t = 0\) for \(i = k+1, \ldots, d\) then \(V_t(\varphi) = \sum_{i=1}^k \xi^i_t S^i_t + \psi^0_t B^0_t\) and (2.28) yields

\[dF_t(\varphi) = r^0_t \left( V_t(\varphi) - \sum_{i=1}^k \xi^i_t S^i_t \right) dt - \sum_{i=k+1}^d \xi^i_t r^i_t S^i_t dt.\]

### 2.3 Different Lending and Borrowing Cash Rates

We now modify our model by postulating that the unsecured borrowing and lending cash rates are different. Recall that we denoted by \(B^{0,+}\) and \(B^{0,-}\) the account processes corresponding to the lending and borrowing rates, respectively. It is now natural to represent a portfolio \(\varphi\) as \(\varphi = (\xi^1, \ldots, \xi^d, \psi^{0,+}, \psi^{0,-}, \psi^1, \ldots, \psi^d)\) where, by assumption, \(\psi^{0,+}_t \geq 0\) and \(\psi^{0,-}_t \leq 0\) for all \(t \in [0,T]\). Moreover, since simultaneous lending and borrowing of cash is either precluded or not efficient (if \(\psi^{0,-}_t \geq r^{0,+}\)), we also postulate that \(\psi^{0,+}_t \psi^{0,-}_t = 0\) for all \(t \in [0,T]\). The wealth process of a portfolio \(\varphi\) now equals

\[V_t(\varphi) = \sum_{i=1}^d \xi^i_t S^i_t + \sum_{i=1}^d \psi^i_t B^i_t + \psi^{0,+}_t B^{0,+}_t + \psi^{0,-}_t B^{0,-}_t, \quad (2.29)\]

and the self-financing condition reads

\[
V_t(\varphi) = V_0(\varphi) + \sum_{i=1}^d \int_{(0,t]} \xi^i_u d(S^i_u + A^i_u) + \sum_{i=1}^d \int_{(0,t]} \psi^i_u dB^i_u \\
+ \int_{(0,t]} \psi^{0,+}_u dB^{0,+}_u + \int_{(0,t]} \psi^{0,-}_u dB^{0,-}_u + A_t. \quad (2.30)
\]

It is worth noting that \(\psi^{0,+}_t\) and \(\psi^{0,-}_t\) satisfy

\[\psi^{0,+}_t = (B^{0,+}_t)^{-1} \left( V_t(\varphi) - \sum_{i=1}^d \xi^i_t S^i_t - \sum_{i=1}^d \psi^i_t B^i_t \right)^+\]

and

\[\psi^{0,-}_t = -(B^{0,-}_t)^{-1} \left( V_t(\varphi) - \sum_{i=1}^d \xi^i_t S^i_t - \sum_{i=1}^d \psi^i_t B^i_t \right)^-.\]

The following corollary furnishes the wealth dynamics in the present set-up.
Corollary 2.2 (i) Assume that $B^{0,+}$ and $B^{0,-}$ are account processes corresponding to the lending and borrowing rates. Let $\varphi$ be any self-financing strategy such that $\psi_i^{0,+} \geq 0$, $\psi_i^{0,-} \leq 0$ and $\psi_i^{0,+} \psi_i^{0,-} = 0$ for all $t \in [0,T]$. Then the wealth process $V(\varphi)$, which is given by (2.29), has the following dynamics

$$dV_t(\varphi) = \sum_{i=1}^{d} \xi_t^i B_t^i d\hat{S}_t^{i,clrd} + \sum_{i=1}^{d} \zeta_t^i (B_t^i)^{-1} dB_t^i + dA_t$$

$$+ \left(V_t(\varphi) - \sum_{i=1}^{d} \xi_t^i S_t^i - \sum_{i=1}^{d} \psi_t^i B_t^i \right)^+ (B_t^{0,+})^{-1} dB_t^{0,+} \tag{2.31}$$

$$- \left(V_t(\varphi) - \sum_{i=1}^{d} \xi_t^i S_t^i - \sum_{i=1}^{d} \psi_t^i B_t^i \right)^- (B_t^{0,-})^{-1} dB_t^{0,-}.$$  

(ii) If, in addition, $\psi_t^i = 0$ for $i = 1, \ldots, k$ and $\zeta_t^i = 0$ and $i = 1, \ldots, d$ for all $t \in [0,T]$ then

$$dV_t(\varphi) = \sum_{i=1}^{k} \xi_t^i d(S_t^i + A_t^i) + \sum_{i=k+1}^{d} \xi_t^i B_t^i d\hat{S}_t^{i,clrd} + dA_t$$

$$+ \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ (B_t^{0,+})^{-1} dB_t^{0,+} - \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- (B_t^{0,-})^{-1} dB_t^{0,-}. \tag{2.32}$$

Proof. Formula (2.31) can be derived from (2.30) using also equality (see (2.19))

$$B_t^i d\hat{S}_t^{i,clrd} = dS_t^i - \hat{S}_t^i dB_t^i + dA_t.$$  

We omit the details. \hfill \Box

Example 2.3 Under the assumptions of part (ii) in Corollary 2.2 if, in addition, all account processes $B_t^i$ for $i = 1, k + 2, \ldots, d + 2$ are absolutely continuous then (2.32) becomes

$$dV_t(\varphi) = \sum_{i=1}^{k} \xi_t^i (dS_t^i + dA_t^i) + \sum_{i=k+1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dA_t$$

$$+ r_t^{0,+} \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ dt - r_t^{0,-} \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- dt \tag{2.33}$$

and thus the funding costs satisfy

$$dF_t(\varphi) = r_t^{0,+} \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ dt - r_t^{0,-} \left(V_t(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- dt - \sum_{i=k+1}^{d} r_t^i \xi_t^i S_t^i dt.$$  

In particular, by setting $k = 0$ we obtain

$$dV_t(\varphi) = \sum_{i=1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dA_t + r_t^{0,+} (V_t(\varphi))^+ dt - r_t^{0,-} (V_t(\varphi))^-. \tag{2.34}$$

2.4 Trading Strategies under Various Forms of Netting

So far, long and short positions in funding accounts $B_t^j$, $j = 0, 1, \ldots, d$ were assumed to bear the same interest. This assumption will be now relaxed, so that we will now deal with the extended framework in which the issue of netting long and short positions in risky assets becomes crucial. Let us first make some comments about the concept of netting of positions and/or exposures. In general,
the concept netting of long and short positions can be introduced at various levels of inclusiveness, from the absence of netting altogether to the most comprehensive case of netting of all positions. For our purposes, it will be enough to consider the following cases:
(a) the absence of any netting of long/short positions,
(b) only netting of long/short positions for each particular risky asset and its funding accounts,
(c) in addition, netting of long/short cash positions for all risky assets that are funded from a given funding account,
(d) in addition, netting of exposures (and thus also margin accounts) associated with all contracts between the counterparties.

2.4.1 Case (a)
To cover the case of the total absence of any netting of long and short positions in any asset \( S^i \), one can postulate that for all \( i = 1, \ldots, d \) and \( t \in [0, T] \),
\[
\xi_t^i S^i_t + \psi_t^i B_t^i = 0, \quad \xi_t^i S^i_t + \psi_t^i B_t^i = 0
\]
where
\[
\xi_t^i S^i_t := -(\xi_t^i S^i_t)^{-} \leq 0, \quad \xi_t^i S^i_t := (\xi_t^i S^i_t)^{+} \geq 0
\]
so that \( \psi_t^i \geq 0 \) and \( \psi_t^i \leq 0 \) for all \( t \in [0, T] \). In particular, even if \( \xi_t^i \geq 0 \) for all \( t \), meaning that the net position in the \( i \)-th asset is null at any time, there will be still an incremental cost of holding open both positions, due to the spread between the accounts \( B_t^i \) and \( B_t^i \). This case is apparently very restrictive and not practical. Hence it will not be analyzed in what follows.

2.4.2 Case (b)
Let us now examine the case (b). To make this set-up non-trivial, we introduce two different accounts, denoted as \( B_t^i \) and \( B_t^i \), which are aimed to reflect the funding costs for the \( i \)-th asset.
We now postulate that
\[
V_t(\varphi) = \psi_t^0 B_t^0 + \psi_t^0 B_t^0 + \sum_{i=1}^d (\xi_t^i S^i_t + \psi_t^i B_t^i + \psi_t^i B_t^i) = \psi_t^0 B_t^0 + \psi_t^0 B_t^0 -
\]
where \( \psi_t^i \geq 0 \) and \( \psi_t^i \leq 0 \) for \( t \in [0, T] \) and, for \( i = 1, 2, \ldots, d \) and \( t \in [0, T] \),
\[
\xi_t^i S^i_t + \psi_t^i B_t^i + \psi_t^i B_t^i = 0. \tag{2.35}
\]
The netting mechanism can be here interpreted as follows: for the purpose of hedging, it is pointless to hold at the same time long and short positions in any asset \( i \); it is enough to take the net position in the \( i \)-th asset. For example, if a bank already holds the short position in some asset and the need to take the long position of the same size arises, we postulate that the short position is first closed. One could notice, however, that this way of trading is not always an optimal from the point of view of minimization of total funding costs. Note also that condition (2.35) prevents netting of short or long cash positions within assets for which long and short funding accounts coincide. See also Remark 2.7 for general comments regarding condition (2.15), which also apply to condition (2.35).

Since simultaneous lending and borrowing of cash from the funding account \( i \) is not allowed (or not efficient if \( r^i \geq r^{i'} \)), we also postulate that \( \psi_t^i \psi_t^{i'} = 0 \) for all \( t \in [0, T] \). This implies that
\[
\psi_t^0 = (B_t^0)^{-1} (V_t(\varphi))^+, \quad \psi_t^0 = -(B_t^0)^{-1} (V_t(\varphi))^-
\]
and, for every \( i = 1, 2, \ldots, d \),
\[
\psi_t^i = (B_t^i)^{-1} (\xi_t^i S^i_t)^{-}, \quad \psi_t^i = -(B_t^i)^{-1} (\xi_t^i S^i_t)^{+}. \tag{2.37}
\]
The self-financing condition reads

\[ V_t(\varphi) = V_0(\varphi) + \sum_{i=1}^{d} \int_{(0,t]} \xi_i^t \, d(S_i^t + A_i^t) + \sum_{i=0}^{d} \int_{(0,t]} \psi_i^{t+} \, dB_i^{t+} + \sum_{i=0}^{d} \int_{(0,t]} \psi_i^{t-} \, dB_i^{t-} + A_t. \]

Hence the following result is straightforward.

**Corollary 2.3** Assume that \( B_i^{t+} \) and \( B_i^{t-} \) are account processes corresponding to the lending and borrowing rates. We postulate that \( \psi_i^{t+} \geq 0, \psi_i^{t-} \leq 0 \) and \( \psi_i^{t+} \psi_i^{t-} = 0 \) for all \( i = 0,1,\ldots,d \) and \( t \in [0,T] \), and equality \((2.32)\) holds for all \( i = 1,2,\ldots,d \). Then the wealth process equals, for all \( t \in [0,T] \),

\[ V_t(\varphi) = \psi_t^{0+} B_t^{0+} + \psi_t^{0-} B_t^{0-} \]

and the wealth dynamics are

\[
dV_t(\varphi) = \sum_{i=1}^{d} \xi_i^t \, d(S_i^t + A_i^t) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- (B_i^{t+})^{-1} \, dB_i^{t+} - \sum_{i=1}^{d} (\xi_i^t S_i^t)^+ (B_i^{t-})^{-1} \, dB_i^{t-} - (V_t(\varphi))^+ (B_t^{0+})^{-1} \, dB_t^{0+} - (V_t(\varphi))^- (B_t^{0-})^{-1} \, dB_t^{0-} + dA_t. \tag{2.38}
\]

**Remark 2.8** When the equality \( B_i^{t+} = B_i^{t-} = B_i^t \) for all \( i = 1,2,\ldots,d \) then formula \((2.38)\) can be seen as a special case of formula \((2.31)\) with \( \zeta_i^t = 0 \) for all \( i \) (see also dynamics \((2.34)\)).

**Example 2.4** Under the assumptions of Corollary \((2.3)\) if, in addition, all account processes \( B_i^{t+} \) and \( B_i^{t-} \) for \( i = 0,1,\ldots,d \) are absolutely continuous then \((2.38)\) becomes (note that \((2.39)\) extends \((2.34)\))

\[
dV_t(\varphi) = \sum_{i=1}^{k} \xi_i^t (d(S_i^t + A_i^t)) + \sum_{i=1}^{d} r_i^{t+} (\xi_i^t S_i^t)^- \, dt - \sum_{i=1}^{d} r_i^{t-} (\xi_i^t S_i^t)^+ \, dt \tag{2.39}
\]

and thus the funding costs satisfy

\[
dF_t(\varphi) = r_t^{0+} (V_t(\varphi))^+ \, dt - r_t^{0-} (V_t(\varphi))^- \, dt + \sum_{i=1}^{d} r_i^{t+} (\xi_i^t S_i^t)^- \, dt - \sum_{i=1}^{d} r_i^{t-} (\xi_i^t S_i^t)^+ \, dt.
\]

**2.4.3 Case (c)**

We will examine here a special case of convention (c), which seems to be of some interest in practice. We now assume that \( B_i^{t+} = B_i^{t-} \) for all \( i = 1,2,\ldots,d \) and we postulate that all short cash positions in risky assets \( S_1,\ldots,S_d \) are aggregated. This means that all positive cash amounts available, inclusive of proceeds from short-selling of risky assets, are included in the wealth and invested in accounts \( B_i^{0+} \) or \( B_i^{0-} \). By contrast, long cash positions in risky assets \( S_i \) are assumed to be funded from respective funding accounts \( B_i^{t-} \). We thus deal here with the case of the partial netting of positions across risky assets.

To formally describe the present set-up, we postulate that

\[ V_t(\varphi) = \psi_t^{0+} B_t^{0+} + \psi_t^{0-} B_t^{0-} + \sum_{i=1}^{d} (\xi_i^t S_i^t + \psi_i^{t-} B_i^{t-}) \]

where, for every \( i = 1,2,\ldots,d \) and \( t \in [0,T] \), the process \( \psi_i^{t-} \) satisfies

\[ \psi_i^{t-} = -(B_i^{t-})^{-1} (\xi_i^t S_i^t)^+ \leq 0. \tag{2.40} \]
so that also

$$V_t(\varphi) = \psi_t^{0,+} B_t^{0,+} + \psi_t^{0,-} B_t^{0,-} - \sum_{i=1}^{d} (\xi_i^t S_t^i)^-.$$ 

Since, as usual, it is postulated that $\psi_t^{0,+} \geq 0$ and $\psi_t^{0,-} \leq 0$, we obtain the following equalities

$$\psi_t^{0,+} = (B_t^{0,+})^{-1} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^+, \quad \psi_t^{0,-} = -(B_t^{0,-})^{-1} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^-. $$

Finally, the self-financing condition is given by the following expression

$$V_t(\varphi) = V_0(\varphi) + \sum_{i=1}^{d} \int_{(0,t]} \xi_i^t d(S_u^i + A_u^i) + \sum_{i=0}^{d} \int_{(0,t]} \psi_i^t - dB_i^t$$

$$+ \int_{(0,t]} \psi_0^{0,+} dB_0^{0,+} + \int_{(0,t]} \psi_0^{0,-} dB_0^{0,-} + A_t.$$ 

The following result yields the wealth dynamics in the present set-up.

**Corollary 2.4** Under the present assumptions, the wealth dynamics are

$$dV_t(\varphi) = \sum_{i=1}^{d} \xi_i^t (dS_t^i + dA_t) - \sum_{i=1}^{d} (\xi_i^t S_t^i)^+(B_t^{0,+})^{-1} dB_t^{0,+} + dA_t$$

$$(2.41)$$

$$+ \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^+(B_t^{0,+})^{-1} dB_t^{0,+} - \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^-(B_t^{0,-})^{-1} dB_t^{0,-}.$$ 

Note that even if we assume, in addition, that $B_t^{i,-} = B_0^{0,-}$ for all $i = 1, 2, \ldots, d$, expression $2.41$ does not reduce to $2.31$, since condition $2.40$ precludes netting of long cash positions across risky assets.

**Example 2.5** Under the assumptions of Corollary 2.4 if, in addition, all account processes $B_t^{i,+}$ and $B_t^{0,-}$ are absolutely continuous then $2.41$ becomes

$$dV_t(\varphi) = \sum_{i=1}^{k} \xi_i^t (dS_t^i + dA_t) - \sum_{i=1}^{d} r_t^i (\xi_i^t S_t^i)^+ dt + dA_t$$

$$(2.42)$$

$$+ r_t^{0,+} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^+ dt - r_t^{0,-} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^- dt$$

and thus the funding costs satisfy

$$dF_t(\varphi) = r_t^{0,+} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^+ dt - r_t^{0,-} \left( V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S_t^i)^- \right)^- dt - \sum_{i=1}^{d} r_t^{i,-} (\xi_i^t S_t^i)^+ dt.$$ 

### 2.5 Trading Strategies with Collateralization

In this section, we will address the situation when the hedger enters a contract with contractual cash flows $A$ and either receives or posts the cash collateral, which, we assume, is specified by some stochastic process $C$. Let

$$C_t = C_t 1_{\{C_t \geq 0\}} - C_t 1_{\{C_t < 0\}} = C_t^+ - C_t^-$$

(2.43)
be the usual decomposition of $C_t$ into the positive and negative components. By convention, $C_t^+$ stands for the cash value of collateral received, whereas $C_t^-$ represents the cash value of collateral posted. The mechanism of posting or receiving collateral is referred to as *margining*.

In Section 2.3 we work under the following standing assumptions:

- (a) the lending and borrowing cash rates $B_0^{0,+}$ and $B_0^{0,-}$ may be identical or they may differ,
- (b) the long and short funding rates for each risky asset are identical: $B_t^{i,+} = B_t^{i,-} = B_t^i$.

Assumption (b) implies that the issue of netting of long and short cash positions in a given risky asset is only relevant for assets funded from the cash account (i.e., with $\psi_t = 0$) and this kind of netting is postulated throughout. Of course, the computations related to the funding of collateral can be combined with any convention regarding netting of cash positions.

### 2.5.1 Generic Margin Account

Let $B_t^{C,+}, B_t^{H,+}, B_t^{C,-}$ and $B_t^{H,-}$ be strictly positive, continuous processes of finite variation. It is easy to see that it suffices to account in the dynamics of the wealth process for additional gains or losses associated with the variations in the margin account through a minor extension of Definition 2.1. To this end, we introduce a collateralized trading strategy $(\varphi, A, C)$ where we set

$$\varphi = (\xi_1^I, \ldots, \xi_d^I, \psi_0^I, \ldots, \psi_d^I, \psi_t^{C,+}, \psi_t^{C,-}, \psi_t^{H,+}, \psi_t^{H,-}).$$

A portfolio $\varphi$ is composed of assets $S_i^I$, $i = 1, 2, \ldots, d$, the unsecured account $B_0^I$, the funding accounts $B_j^I$, $j = 1, 2, \ldots, d$, and the collateral accounts $B_t^{C,+}, B_t^{H,+}, B_t^{C,-}$ and $B_t^{H,-}$. The goal of the next definition is merely to introduce additional notation used when analyzing collateralization and rehypothecation. More detailed specification of processes $\psi_t^{C,+}, \psi_t^{C,-}, \psi_t^{H,+}$ and $\psi_t^{H,-}$ and their financial interpretation will be discussed in the foregoing subsections. For simplicity, in Definition 2.2 we assume that $B_0^{0,+} = B_0^{0,-} = B_0^0$. This temporary assumption will be later relaxed.

**Definition 2.2** A collateralized trading strategy $(\varphi, A, C)$ with $\varphi$ given by (2.44) is self-financing whenever its wealth process $V(\varphi)$, which is given by the equality

$$V_t(\varphi) = \sum_{i=1}^d \xi_i^I S_i^I + \sum_{j=0}^d \psi_j^I B_j^I + \psi_t^{C,+} B_t^{C,+} + \psi_t^{C,-} B_t^{C,-} + \psi_t^{H,+} B_t^{H,+} + \psi_t^{H,-} B_t^{H,-},$$

satisfies, for every $t \in [0, T]$

$$V_t(\varphi) = V_0(\varphi) + \sum_{i=1}^d \int_{(0,t]} \xi_i^I d(S_i^I + A_i^I) + \sum_{j=0}^d \int_{(0,t]} \psi_j^I dB_j^I + A_t$$

$$+ \int_{(0,t]} \psi_t^{C,+} dB_t^{C,+} + \int_{(0,t]} \psi_t^{C,-} dB_t^{C,-} + \int_{(0,t]} \psi_t^{H,+} dB_t^{H,+} + \int_{(0,t]} \psi_t^{H,-} dB_t^{H,-}.$$  

Definition 2.2 is fairly general, so that it can be used to examine various alternative market conventions that either occur or might occur in practice. In Proposition 2.4 we will derive more explicit representation for the wealth dynamics under segregation, that is, under the assumption of restricted use of cash collateral when the hedger is collateral taker. Subsequently, in Proposition 2.3 we will address the issue of collateral trading with rehypothecation. Proposition 2.4 which deals with the case of partial rehypothecation, covers Propositions 2.2 and 2.3 as special cases and thus the proofs of Propositions 2.2 and 2.3 are omitted.

### 2.5.2 Alternative Specifications of Collateral Amount

In market practice, the collateral amount is typically specified in terms of the mark-to-market value of a hedged contract, whose value at time $t$ is henceforth denoted as $M_t$. In this case, we can write

$$C_t = (1 + \delta_1^I) M_t 1_{\{M_t > 0\}} - (1 + \delta_2^I) M_t 1_{\{M_t < 0\}} = (1 + \delta_1^I) M_t^+ - (1 + \delta_2^I) M_t^-$$

(2.47)
for some haircut processes $\delta^1$ and $\delta^2$. In our theoretical framework, the goal is to develop valuation of a contract through its hedging, so that it seems natural to tie the mark-to-market value to the (yet unknown) value of a contract. Since the wealth process $V(\varphi)$ is aimed to cover future liabilities of the hedger, the stylized ‘market value’ of a contract, as seen by the hedger, coincides with the negative of his wealth. Consequently, it makes sense to formally identify the mark-to-market value $M$ as seen from the hedger’s perspective, with the negative of the wealth process of hedging strategy. If we set $M = -V(\varphi)$ then formula \[2.47\] becomes

$$C_t = C_t(\varphi) := (1 + \delta_1^t) V_t^-(\varphi) - (1 + \delta_2^t) V_t^+(\varphi). \quad (2.48)$$

The case of the fully collateralized contract corresponds to equalities $\delta_1^t = \delta_2^t = 0$ for all $t$, which in turn imply that the equality $C_t = -V(\varphi)$ holds. The collateral amount in \[2.48\] is seen from the perspective of the hedger, and thus it depends here on hedger’s trading strategy $\varphi$. Of course, an analogous analysis can be done for the counterparty. However, since market conditions (in particular, funding rates) are typically different for the two parties, it is not likely that their computations of the contract’s value (and thus also the collateral amount) will yield the same outcome.

### 2.5.3 Collateral Trading with Segregated Accounts

The current financial practice typically requires the collateral amounts to be held in segregated margin accounts, so that the hedger, as collateral taker, cannot use it for purchasing risky assets, but is required to put it in the account $B^{H,+}$. In addition, we assume that if the hedger is a collateral giver then he needs to borrow the required amount from a predetermined account $B^{H,-}$. Under these assumptions, the right-hand side in \[2.48\] should not explicitly depend on the collateral process. Formally, we postulate that the following conditions are met, for all $t \in [0, T]$,

$$\psi^C_t C^+_t + \psi^H_t H^+_t = 0, \quad (2.49)$$

and

$$\psi^C_t C^-_t + \psi^H_t H^-_t = 0. \quad (2.50)$$

An important practical case, in which the above conditions are satisfied, is described in Proposition \[2.2\] We assume henceforth that the collateral accounts $B^{C,+}, B^{H,+}, B^{C,-}$ and $B^{H,-}$ are subject to the following interpretation:

- If the hedger receives collateral then he pays to the other party interest determined by the level of $C^+$ and the account $B^{C,+}$ and he invests the collateral amount in the account $B^{H,+}$.
- If the hedger is required to post collateral then he borrows the collateral amount $C^-$ at the interest specified by $B^{H,-}$ and he receives interest payments determined by the level of $C^-$ and the account $B^{C,-}$.

The next proposition is a rather straightforward extension of Proposition \[2.1\] Since this result is easy to establish by combining Corollary \[2.1\] with Definition \[2.2\] we omit the proof. Note that equalities \[2.51\] \-- \[2.52\] ensure that conditions \[2.49\] \-- \[2.50\] are indeed satisfied.

**Proposition 2.2** Assume that a trading strategy $(\varphi, A, C)$, with the process $\varphi$ given by \[2.44\], is self-financing and the following equalities hold, for every $t \in [0, T]$,

$$\psi^C_t = -(B^C_t)^{-1} C^+_t, \quad \psi^C_t = (B^C_t)^{-1} C^-_t, \quad (2.51)$$

$$\psi^H_t = (B^H_t)^{-1} C^+_t, \quad \psi^H_t = -(B^H_t)^{-1} C^-_t. \quad (2.52)$$

Then the wealth process $V(\varphi)$ equals, for every $t \in [0, T]$,

$$V_t(\varphi) = \sum_{i=1}^d \xi^i_t S^i_t + \sum_{j=0}^d \psi^j_t B^j_t \quad (2.53)$$
and it admits the following decomposition

\[ V_t(\varphi) = V_0(\varphi) + G_t(\varphi) + F_t(\varphi) + F_t^C + A_t \]  

(2.54)

where \( G_t(\varphi) \) is given by (2.6), \( F_t(\varphi) \) satisfies (2.23), and the funding costs of the margin account, denoted as \( F^C \), equal

\[ F_t^C = \int_{[0,t]} C^+_u \left( (B^C_u)^{-1} dB^C_u + (B^C_u)^{-1} dB^C_u \right) - \int_{[0,t]} C^-_u \left( (B^H_u)^{-1} dB^H_u + (B^C_u)^{-1} dB^C_u \right). \]

More explicitly, the dynamics of the wealth process \( V(\varphi) \) are

\[ dV_t(\varphi) = \tilde{V}_t(\varphi) dB^0_t + \sum_{i=1}^d \xi^i_t dK^i_t + \sum_{i=1}^d \zeta^i_t (\tilde{B}^i_t)^{-1} dB^C_t + dF_t^C + dA_t. \]  

(2.55)

In particular, under assumption (2.14) we obtain

\[ dV_t(\varphi) = \tilde{V}_t(\varphi) dB^0_t + \sum_{i=1}^d \xi^i_t dK^i_t + dF_t^C + dA_t. \]  

(2.56)

Let us define the collateral-adjusted cash flows \( A^C \) by setting \( A^C = A + F^C \), so that \( V(\varphi) = V_0(\varphi) + G(\varphi) + F(\varphi) + A^C \). Although the funding cost of collateral \( F^C \) will typically depend on the choice of a hedging strategy \( \varphi \), in order to keep our notation simple, we do not emphasize this dependence explicitly in the notation of \( F^C \) and \( A^C \). The definitions and results of Section 2.1 remain valid if we replace \( A \) by \( A^C \), provided that the wealth process \( V(\varphi) \) satisfies (2.53), that is, assuming segregation of collateral. A trading strategy \( (\varphi, A, C) \) satisfying Definition 2.2 as well as satisfying the segregation of collateral requirement, can thus formally be reduced to the pair \( (\varphi, A^C) \) satisfying Definition 2.1.

In particular, the cumulative wealth process \( V^{\text{clld}}(\varphi) \) is defined through the following modification of formula (2.8)

\[ V^{\text{clld}}_t(\varphi) := V_t(\varphi) - B^0_t \int_{[0,t]} (B^0_u)^{-1} dA^C_u. \]  

(2.57)

Such reduction comes in handy when the collateral process \( C \) is independent of the choice of a portfolio \( \varphi = (\xi^1, \ldots, \xi^d, \psi^0, \ldots, \psi^d) \). In that case, the valuation and hedging of a derivative security will simultaneously cover the cash flows of the contract and funding costs of collateral.

**Example 2.6** We place ourselves within the set-up of Example 2.1 and we postulate, in addition, that the processes \( B^{C,+}, B^{H,+}, B^{C,-} \) and \( B^{H,-} \) are absolutely continuous, so that

\[ dB^{C,+}_t = r^{C,+}_t B^{C,+}_t \, dt, \quad dB^{H,+}_t = r^{H,+}_t B^{H,+}_t \, dt, \]
\[ dB^{C,-}_t = r^{C,-}_t B^{C,-}_t \, dt, \quad dB^{H,-}_t = r^{H,-}_t B^{H,-}_t \, dt, \]

for some interest rate processes \( r^{C,+}, r^{H,+}, r^{C,-} \) and \( r^{H,-} \). Then

\[ F_t^C = \int_0^t (r^{H,+}_u - r^{C,+}_u) C^+_u \, du - \int_0^t (r^{H,-}_u - r^{C,-}_u) C^-_u \, du. \]  

(2.58)

Suppose that condition (2.14) is satisfied. Then, from (2.56), we obtain

\[ dV_t(\varphi) = r^0_t V_t(\varphi) \, dt + \sum_{i=1}^d \xi^i_t (dS^i_t - r^i_t S^i_t \, dt + dA^i_t) + dF_t^C + dA_t. \]  

(2.59)

In the special case when \( r^{H,+} = r^{H,-} = r^0 \) and \( r^{C,+} = r^{C,-} = r^C \), formula (2.58) simplifies to

\[ F_t^C = \int_0^t (r^0_u - r^C_u) C_u \, du. \]  

(2.60)
and thus (2.61) becomes

\[ dV_t(\varphi) = r^0_t V_t(\varphi) dt + \sum_{i=1}^d \xi^i_t (dS^i_t - r^i_t S^i_t dt + dA^i_t) + (r^0_t - r^C_t) C_t dt + dA_t. \]  

(2.61)

Recall that the case of the fully collateralized contract corresponds to the equality \( C = C(\varphi) = -V(\varphi) \). Under this additional assumption, formula (2.61) reduces to

\[ dV_t(\varphi) = r^C_t V_t(\varphi) dt + \sum_{i=1}^d \xi^i_t (dS^i_t - r^i_t S^i_t dt + dA^i_t) + dA_t. \]  

(2.62)

Consequently, the funding costs inclusive of the gains/losses from the margin account for the fully collateralized contract, as seen by the hedger, are

\[ F_t(\varphi) + F^C_t(\varphi) = \int_0^t r^C_u V_u(\varphi) du - \sum_{i=1}^d \xi^i_u r^i_u S^i_u du. \]  

(2.63)

In a more general situation, when \( C(\varphi) = \alpha V(\varphi) \) for some \( \mathcal{G}\)-adapted process \( \alpha \), we obtain

\[ F^C_t(\varphi) = \int_0^t (r^0_u - r^C_u) \alpha_u V_u(\varphi) du \]  

(2.64)

and thus the wealth of a partially collateralized contract is governed by the equation

\[ dV_t(\varphi) = \left((1 + \alpha_t)r^0_t - \alpha_t r^C_t\right)V_t(\varphi) dt + \sum_{i=1}^d \xi^i_t (dS^i_t - r^i_t S^i_t dt + dA^i_t) + dA_t. \]  

(2.65)

Consequently, the total funding costs of a self-financing trading strategy \((\varphi, A, \alpha V(\varphi))\) are

\[ F_t(\varphi) + F^C_t(\varphi) = \int_0^t \left((1 + \alpha_u)r^0_u - \alpha_u r^C_u\right) V_u(\varphi) du - \sum_{i=1}^d \int_0^t \xi^i_u r^i_u S^i_u du. \]  

(2.66)

Note that the set-up considered in this example can also be easily combined with the set-up of Example 2.2.

### 2.5.4 Collateral Trading with Full Rehypothecation

Rehypothecation is a practice where a bank reuses the collateral pledged by its counterparties as collateral for its own borrowing. In our stylized approach to funding effects of rehypothecation, it is natural to assume instead that the hedger, when he is a collateral taker, is granted an unrestricted use of the full collateral amount \( C^+ \). Put another way, the collateral received can be seen as an ordinary component of a hedger’s trading strategy (of course, this applies only prior to counterparty’s default). As before, the hedger pays interest on the amount \( C^+ \) to the counterparty at the rate determined by the process \( B^{C^+} \). Furthermore, we assume that any traded asset can be posted when the hedger is a collateral giver and when he posts collateral then he is entitled to interest payments, as specified by the process \( B^{C^-} \). Note that equality (2.68) reflects the fact that the total amount \( V^C_t(\varphi) := V_t(\varphi) + C_t \) can now be used for trading in risky assets by the hedger, where \( V(\varphi) \) stands for the wealth process exclusive of the collateral amount. This feature makes the present situation different from modeling assumptions considered so far. The result stated below can be deduced from Proposition 2.3 and thus we omit the proof.

**Proposition 2.3** Assume that a trading strategy \((\varphi, A, C)\) with \( \varphi \) given by (2.44) is self-financing and the following equalities hold:

\[ \psi^C_+ = -C_+^+(B_{-}^{C^+})^{-1}, \quad \psi^C_- = C_-^-(B_{-}^{C^-})^{-1}, \quad \psi^H_+ = \psi^H_- = 0, \]  

(2.67)
so that the wealth process \( V(\varphi) \) satisfies

\[
V_t(\varphi) = \sum_{i=1}^{d} \xi_i^t S^i_t + \sum_{j=0}^{d} \psi_j^t B_j^t - C_t
\]  

(2.68)

or, equivalently,

\[
V_t^C(\varphi) = \sum_{i=1}^{d} \xi_i^t S^i_t + \sum_{j=0}^{d} \psi_j^t B_j^t.
\]  

(2.69)

Then \( V(\varphi) \) satisfies, for every \( t \in [0, T] \),

\[
V_t(\varphi) = V_0(\varphi) + G_t(\varphi) + F_t(\varphi) + F_t^C + A_t
\]  

(2.70)

where \( G_t(\varphi) \) is given by (2.4), \( F_t(\varphi) \) satisfies (2.23) with \( \overline{V}(\varphi) \) replaced by \( \overline{V}^C(\varphi) = (B^0)^{-1}V^C(\varphi) \), and the funding costs of collateral are given by

\[
F_t^C = \int_{(0,t]} C_u^{-1} (B_u^{C,-})^{-1} dB_u^{C,-} - \int_{(0,t]} C_u^+ (B_u^{C,+})^{-1} dB_u^{C,+},
\]  

(2.71)

or, equivalently,

\[
dV_t(\varphi) = \overline{V}_t^C(\varphi) dB_t^0 + \sum_{i=1}^{d} \xi_i^t dK_i^t + \sum_{i=1}^{d} \zeta_i^t (\overline{B}_i^t)^{-1} d\overline{B}_i^t + dF_t^C + dA_t.
\]  

(2.72)

In particular, under assumption (2.14) the dynamics of \( V(\varphi) \) are

\[
dV_t(\varphi) = \overline{V}_t^C(\varphi) dB_t^0 + \sum_{i=1}^{d} \xi_i^t dK_i^t + dF_t^C + dA_t.
\]  

(2.73)

Example 2.7 We work here under the assumptions of Proposition 2.6. Our goal is to provide extensions of formulae obtained in Examples 2.3 and 2.6. We therefore postulate that the lending and borrowing rates are different (typically, \( r_i^{0,-} > r_i^0 \geq r_i^{0,+} \)). We also assume that \( r_i^0 = r_i^0 \) for \( i = 1, \ldots, k \) and condition (2.15) is satisfied for \( i = k+1, k+2, \ldots, d \). Then the wealth \( V(\varphi) \) equals

\[
V_t(\varphi) = \sum_{i=1}^{k} \xi_i^t S^i_t + \psi_i^{0,+} B^{0,+}_i + \psi_i^{0,-} B^{0,-}_i - C_t
\]

where, by assumption, \( \psi_i^{0,+} \geq 0 \) and \( \psi_i^{0,-} \leq 0 \), and it satisfies

\[
dV_t(\varphi) = \overline{V}_t^{C}(\varphi) dB_t^0 + dF_t^{C}(\varphi) + \sum_{i=k}^{d} \xi_i^t B_i^t d\overline{S}_i^{t,\text{cld}} + \sum_{i=k+1}^{d} \xi_i^t B_i^t d\overline{S}_i^{t,\text{cld}} + dF^C_t + dA_t
\]  

(2.74)

where in turn \( F^C_t \) is given by (2.71) and

\[
dF_{t}^{V,C}(\varphi) = \left( V_t^{C}(\varphi) - \sum_{i=1}^{k} \xi_i^t S^i_t \right)^+ dt - \left( V_t^{C}(\varphi) - \sum_{i=1}^{k} \xi_i^t S^i_t \right)^- dt
\]

(2.75)

Equivalently, the dynamics of the wealth process are

\[
dV_t(\varphi) = r_t^{0,+} \left( V_t^{C}(\varphi) - \sum_{i=1}^{k} \xi_i^t S^i_t \right)^+ dt - r_t^{0,-} \left( V_t^{C}(\varphi) - \sum_{i=1}^{k} \xi_i^t S^i_t \right)^- dt
\]

\[
+ \sum_{i=1}^{k} \xi_i^t (dS^i_t + dA_t) + \sum_{i=k+1}^{d} \xi_i^t (dS^i_t - r_i^t S^i_t dt + dA_t) + dF_t^C + dA_t
\]  

(2.76)
and thus the funding costs satisfy
\[ dF_t(\varphi) = r_t^{0, +} \left( V_t^C(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ dt - r_t^{0, -} \left( V_t^C(\varphi) - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- dt + \sum_{i=k+1}^{d} r_t^i \psi_t^i B_t^i dt. \]

**Example 2.8** We work under the assumptions of Example 2.7 and we postulate, in addition, that we deal with a fully collateralized contract, so that \( C = -V(\varphi) \). Then we obtain the following equalities
\[ V_t^C(\varphi) = \sum_{i=1}^{k} \xi_t^i S_t^i + \psi_t^{0, +} B_t^{0, +} + \psi_t^{0, -} B_t^{0, -} = 0 \]
and
\[ dV_t(\varphi) = r_t^{0, +} \left( - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ dt - r_t^{0, -} \left( - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- dt + \sum_{i=1}^{k} \xi_t^i (dS_t^i + dA_t^i) + \sum_{i=k+1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dF_t^C + dA_t. \]

Consequently, the funding costs are governed by the following equation
\[ dF_t(\varphi) = r_t^{0, +} \left( - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^+ dt - r_t^{0, -} \left( - \sum_{i=1}^{k} \xi_t^i S_t^i \right)^- dt + \sum_{i=k+1}^{d} r_t^i \psi_t^i B_t^i dt. \]
If we now assume that \( r_t^{0, +} = r_t^{0, -} = r^0 \) then we get
\[ \sum_{i=1}^{k} \xi_t^i S_t^i + \psi_t^{0, +} B_t^{0, +} = 0 \]
and
\[ dV_t(\varphi) = \sum_{i=1}^{k} \xi_t^i (dS_t^i - r_t^0 S_t^i + dA_t^i) + \sum_{i=k+1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dF_t^C + dA_t \]
so that
\[ dF_t(\varphi) = - \sum_{i=1}^{k} \xi_t^i r_t^0 S_t^i dt - \sum_{i=k+1}^{d} \xi_t^i r_t^i S_t^i dt = r_t^0 \psi_t^0 B_t^i dt + \sum_{i=k+1}^{d} r_t^i \psi_t^i B_t^i dt. \]
Under an additional assumption that \( r_t^{C, +} = r_t^{C, -} = r^C \), we obtain the following expression
\[ dV_t(\varphi) = r_t^C V_t(\varphi) dt + \sum_{i=1}^{k} \xi_t^i (dS_t^i - r_t^0 S_t^i + dA_t^i) + \sum_{i=k+1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dA_t, \]
which can also be deduced from (2.22). Finally, for \( r^C = r^0 \), we get
\[ dV_t(\varphi) = r_t^0 V_t(\varphi) dt + \sum_{i=1}^{k} \xi_t^i (dS_t^i - r_t^0 S_t^i + dA_t^i) + \sum_{i=k+1}^{d} \xi_t^i (dS_t^i - r_t^i S_t^i dt + dA_t^i) + dA_t, \]
which can be easily identified as a special case of (2.22).
2.5.5 Collateral Trading with Partial Rehypothecation

The amount of assets that can be rehypothecated is sometimes capped; we refer to this situation as the partial rehypothecation. The next result addresses the general case of the partial rehypothecation (equivalently, the case of partial segregation) under different lending and borrowing cash rates. It is thus clear that Proposition 2.4 covers Propositions 2.2 and 2.3 as special cases. Note also that formula (2.80) is a rather straightforward extension of equality (2.31).

Proposition 2.4 Assume that a trading strategy \((\varphi, A, C)\) with \(\varphi\) given by

\[
\varphi = (\xi^1, \ldots, \xi^d, \psi^0, \ldots, \psi^d, \psi^{0,+}, \psi^{0,-}, \psi^{C,+}, \psi^{C,-}, \psi^{H,+}, \psi^{H,-})
\]  

(2.77)

is self-financing and the following equalities hold for all \(t \in [0, T]\): \(\varphi^0_t = 0\),

\[
\psi^{C,+}_t = - (B^{C,+}_t)^{-1} C^+_t, \quad \psi^{C,-}_t = (B^{C,-}_t)^{-1} C^-_t,
\]

\[
\psi^{H,+}_t = (1 - \beta_t)(B^{H,+}_t)^{-1} C^+_t, \quad \psi^{H,-}_t = -(1 - \gamma_t)(B^{H,-}_t)^{-1} C^-_t,
\]

for some \(\mathbb{G}\)-adapted stochastic processes \(\beta\) and \(\gamma\), so that the wealth process \(V(\varphi)\) equals

\[
V_t(\varphi) = \sum_{i=1}^d \xi^i_t S^i_t + \sum_{i=1}^d \psi^i_t B^i_t + \psi^{0,+}_t B^{0,+}_t + \psi^{0,-}_t B^{0,-}_t - (\beta_t C^+_t - \gamma_t C^-_t).
\]  

(2.78)

We assume that \(\psi^{0,+}_t \geq 0\), \(\psi^{0,-}_t \leq 0\) and \(\psi^{0,+}_t \psi^{0,-}_t = 0\) for all \(t \in [0, T]\) and

\[
V_t(\varphi) = \sum_{i=1}^d \xi^i_t d(S^i_t + A^i_t) + \sum_{i=1}^d \psi^i_t dB^i_t + \psi^{0,+}_t dB^{0,+}_t + \psi^{0,-}_t dB^{0,-}_t + A_t
\]

\[
+ \psi^{C,+}_t dB^{C,+}_t + \psi^{C,-}_t dB^{C,-}_t + \psi^{H,+}_t dB^{H,+}_t + \psi^{H,-}_t dB^{H,-}_t.
\]  

(2.79)

Then the wealth process \(V(\varphi)\) satisfies

\[
dV_t(\varphi) = \sum_{i=1}^d \xi^i_t B^i_t d\hat{S}^{i,cld}_t + \sum_{i=1}^d \xi^i_t (B^i_t)^{-1} dB^i_t + \psi^{0,+}_t dB^{0,+}_t + dB^{0,-}_t + A_t + \psi^{0,-}_t dB^{0,-}_t
\]

\[
- C^+_t (B^{C,+}_t)^{-1} dB^{C,+}_t - C^-_t (B^{C,-}_t)^{-1} dB^{C,-}_t
\]

\[
+ (1 - \beta_t) C^+_t (B^{H,+}_t)^{-1} dB^{H,+}_t - (1 - \gamma_t) C^-_t (B^{H,-}_t)^{-1} dB^{H,-}_t
\]

(2.80)

where the processes \(\psi^{0,+}_t\) and \(\psi^{0,-}_t\) are given by the following expressions

\[
\zeta^{d+1}_t = \psi^{0,+}_t B^{0,+}_t = \left( V_t(\varphi) - \sum_{i=1}^d \xi^i_t S^i_t - \sum_{i=1}^d \psi^i_t B^i_t + \beta_t C^+_t - \gamma_t C^-_t \right)^+
\]  

(2.81)

and

\[
\zeta^{d+2}_t = \psi^{0,-}_t B^{0,-}_t = - \left( V_t(\varphi) - \sum_{i=1}^d \xi^i_t S^i_t - \sum_{i=1}^d \psi^i_t B^i_t + \beta_t C^+_t - \gamma_t C^-_t \right)^-.
\]  

(2.82)

Proof. First, we establish equalities (2.81) and (2.82) using (2.78) and our assumption: for all \(t \in [0, T]\)

\(\psi^{0,+}_t \geq 0\), \(\psi^{0,-}_t \leq 0\), \(\psi^{0,+}_t \psi^{0,-}_t = 0\).

Next, we recall that (see (2.19))

\[
B^i_t d\hat{S}^{i,cld}_t = dS^i_t - \hat{S}^i_t dB^i_t + dA^i_t.
\]

Formula (2.80) now follows from (2.79) by straightforward computations. \(\square\)
The following corollary to Proposition 2.4 is immediate. Corollary 2.5 deals with the case when risky assets $S^i$ for $i = 1, 2, \ldots, k$ are traded using cash accounts $B_0^0$, whereas risky assets $S^i$ for $i = k+1, k+2, \ldots, d$ are traded using respective funding accounts $B^i$. Of course, it is not hard to extend this result to the case of the market model in which we have two funding accounts, $B^\ast_+ + B^\ast_-$, for each risky asset $S^i$ for $i = k+1, k+2, \ldots, d$.

**Corollary 2.5** Under the assumptions of Proposition 2.4 we postulate, in addition, that $\psi^i = 0$ for $i = 1, 2, \ldots, k$ and condition (2.14) holds for $i = k+1, k+2, \ldots, k$. Then the wealth process $V(\phi)$ satisfies

\[
dV_i(\phi) = \sum_{i=1}^{k} \xi_i^i (dS_i^i + dA_i^i) + \sum_{i=k+1}^{d} \xi_i^i (dS_i^i - r_i^i S_i^i dt + dA_i^i) + dA_t
\]

\[
+ \left( V_i(\phi) - \sum_{i=1}^{k} \xi_i^i S_i^i + \beta_i C_i^+ - \gamma_i C_i^- \right)^+ (B_i^0)^{-1} dB_i^0 +
\]

\[- \left( V_i(\phi) - \sum_{i=1}^{k} \xi_i^i S_i^i + \beta_i C_i^+ - \gamma_i C_i^- \right)^- (B_i^0)^{-1} dB_i^0 +
\]

\[- C_i^+ (B_i^0)^{-1} dB_i^{C,+} + C_i^- (B_i^0)^{-1} dB_i^{C,-} + (1 - \beta_i) C_i^+ (B_i^{H,0}) dB_i^{H,+} - (1 - \gamma_i) C_i^- (B_i^{H,0}) dB_i^{H,-}.
\]

**Example 2.9** We work here under the assumptions of Corollary 2.5. A more explicit representation for the wealth dynamics is readily available when account processes are absolutely continuous.

It is immediate to see that

\[
dV_i(\phi) = \sum_{i=1}^{k} \xi_i^i (dS_i^i + dA_i^i) + \sum_{i=k+1}^{d} \xi_i^i (dS_i^i - r_i^i S_i^i dt + dA_i^i) + dA_t
\]

\[
+ \left[ V_i(\phi) - \sum_{i=1}^{k} \xi_i^i S_i^i + \beta_i C_i^+ - \gamma_i C_i^- \right]^+
\]

\[- \left[ V_i(\phi) - \sum_{i=1}^{k} \xi_i^i S_i^i + \beta_i C_i^+ - \gamma_i C_i^- \right]^-
\]

\[- \left[ r_i^0 (V_i(\phi) - \sum_{i=1}^{k} \xi_i^i S_i^i + \beta_i C_i^+ - \gamma_i C_i^-) + r_i^{C,+} C_i^+ dt + (1 - \beta_i) r_i^{H,+} C_i^+ dt - (1 - \gamma_i) r_i^{H,-} C_i^- dt.\right.
\]

We note that when $r_i^0 = r_i^{0,-} = r_i^0$ and $\beta_i = \gamma_i = 0$ for all $t \in [0, T]$ then the formula above reduces to equation (2.59) with $F^C$ given by (2.58). Moreover, when $\beta_i = \gamma_i = 1$ for all $t \in [0, T]$ then it coincides with expression (2.71) with $F^C$ given by (2.71). It is clear that other important cases are also covered by Proposition 2.3. In particular, we may now set $C = \alpha V(\phi)$ for some $\mathbb{G}$-adapted stochastic process $\alpha$. Recall that a partially collateralized contract corresponds to equality $C(\phi) = \alpha V(\phi)$ for some process $\alpha$ such that $-1 < \alpha < 0$. One can also introduce the fully collateralized contract with haircuts by postulating that (see (2.48))

\[
C_i(\phi) = (1 + 0^i)_i V^i_-(\phi) - (1 + 0^i)_i V^i_+(\phi).
\]

Finally, it is possible to combine the set-up considered in Proposition 2.3 with some convention regarding netting (for instance, the model examined in Section 2.4.3). Needless to say that a large variety of model assumptions can be studied on a case-by-case basis.

### 2.6 Trading Strategy with Funding Benefit at Default

Let us now assume that an investor may default on his contractual obligations before or on the maturity date $T$ of a contract under consideration. In particular, in the case of his default, he will
fail to make a full repayment on his unsecured debt, which is formally represented by a negative position in the unsecured cash account $\bar{B}_{0}^-$. Let $\theta$ be a random time of default and let $R \in [0,1]$ stand for the investor’s recovery rate process (assumed to be $\mathbb{G}$-adapted). It is now natural to assume that all trading activities will stop at a random horizon date $\theta \wedge T$. To account for the investor’s benefit at default time $\theta$, it suffices to introduce the adjusted borrowing account $\bar{B}_{0}^\theta$ by setting $\bar{B}_{0}^\theta = 1$ and

$$d\bar{B}_{t}^\theta = dB_{t}^\theta - B_{t}^\theta (1 - R_t) dH_t$$

(2.83)

where we denote $H_t = \mathbb{1}_{\{t \geq \theta\}}$. It is clear that $\bar{B}_{t}^\theta = B_{t}^\theta$ on the event $\{\theta > t\}$. Note also that the jump of $B_{t}^\theta$ at the random time $\theta$ equals $\Delta \bar{B}_{\theta}^\theta = -(1 - R_{\theta})B_{0}^\theta$. We also replace $\psi_t^0$ by $\theta_t^0$ in dynamics (2.1) in order to make this process $\mathbb{G}$-predictable. Then the non-negative jump of the wealth process $V(\varphi)$, which is caused by the jump of the process $B_{t}^\theta$ at the random time $\theta$, is given by the following expression $\psi_{\theta}^0 \Delta \bar{B}_{\theta}^\theta = -(1 - R_{\theta})\psi_{\theta}^0 B_{\theta}^\theta$. The financial interpretation of this jump is the hedger’s benefit at his own default due to the fact that his debt to the external lender is not repaid in full.

### 2.7 Trading Strategy with Loss at Default

The last step is to describe the loss at the moment of default of either party. In case of a default of either one of the counterparties prior to or maturity of the contract, the contract is terminated and close-out payments are transferred. Since the specification of the close-out payment (and thus also the loss of default) was the topic of numerous papers, we decided not analyze this part of a contract’s specification here. Modeling and arbitrage pricing issues related to the specification of defaults of counterparties, close-out payments, and the impact of benefits at defaults on pricing results will be examined in some detail in the second part of this work.

### 3 Arbitrage-Free Models and Martingale Measures

The goal of the preceding section was to analyze the wealth dynamics for self-financing strategies under alternative assumptions about trading, netting and marking rules. In the next step, we will provide sufficient conditions for the no-arbitrage property of a market model, given the various trading specifications considered above.

#### 3.1 Arbitrage Opportunities under Funding Costs

**Special case.** We first place ourselves in the elementary set-up of Section 2.2 with a single cash account $B^\circ$. Let $\varphi$ be an arbitrary self-financing trading strategy. Then formula (2.20) yields

$$\tilde{V}^\text{cl}(\varphi) = \tilde{V}^\text{cl}(\varphi) + \sum_{i=1}^{d} \int_{(0,t]} \epsilon^i_u \tilde{B}^i_u d\tilde{S}^i_u + \sum_{i=1}^{d} \int_{(0,t]} (\psi^i_u + \epsilon^i_u G^i_u) d\bar{B}^i_u.$$  

(3.1)

Note that dynamics (2.20) of the process $V^\text{cl}(\varphi)$ do not depend on $A$. In addition, we postulate that $\varphi$ is admissible, so that the discounted cumulative wealth process $\tilde{V}^\text{cl}(\varphi)$ is non-negative (or at least bounded from below by a constant). In principle, one may formulate the following general sufficient condition for the arbitrage-free property of the model: for any self-financing trading strategy $\varphi$ there exists a probability measure $\tilde{\mathbb{P}}^\varphi$ on $(\Omega, \mathcal{G}_T)$ such that $\tilde{\mathbb{P}}^\varphi$ is equivalent to $\mathbb{P}$ and the process $\tilde{V}^\text{cl}(\varphi)$ is a $(\tilde{\mathbb{P}}^\varphi, \mathcal{G}_T)$-local martingale. Of course, this condition is rather hard to check, in general, and thus it is not practically appealing. We will thus search for more specific conditions that are relatively easy to verify since they refer to the existence of some universal martingale measure for a given trading set-up (and perhaps also for a given class of contracts at hand).

To this end, we will need first to re-examine the concepts of an arbitrage-free model and arbitrage price since, as we will argue in what follows, the classic notions do not apply to the present non-linear...
framework. In particular, we show that the study of the arbitrage-free property of a market model cannot be separated from the study of hedging strategies for a given class of contracts. The reason is that the presence of incoming or outgoing cash flows associated with a contract have non-additive impact on the dynamics of the wealth process, and thus also on the final gains or losses from trading.

**Remark 3.1** Obviously, if there exists $B^k \neq B^0$ then an arbitrage opportunity arises since we may take $\xi^1 = \ldots = \xi^d = 0$ and $\psi^j = 0$ for every $j$, except for $j = k$. Then we obtain

$$
\tilde{V}_t^{\text{cld}}(\varphi) = \tilde{V}_0^{\text{cld}}(\varphi) + \int_{(0,t]} \psi^k_u d\tilde{B}^k_u
$$

and thus we see that the existence of a local martingale measure for the process $\tilde{V}^{\text{cld}}(\varphi)$ is not ensured, in general. It is thus clear that some additional conditions need to be imposed on the class of trading strategies and/or funding rates to ensure that the model is arbitrage-free.

**General case.** As clear from Remark 3.1, the study of self-financing trading strategies under some form of mixed funding of risky assets is rather cumbersome, in general, so that we need to do it on a case-by-case basis. We may formulate, however, the generic definition of an arbitrage-free market model. We now deal with a model in which the borrowing and lending accounts, $B^{0,+}$ and $B^{0,-}$, are different, in general. Let us observe that an explicit specification of the discounted netted wealth process $\tilde{V}^{\text{cld}}(\varphi, A)$ will depend on additional features of the model at hand. In the present set-up, the netted wealth is defined by the following extension of formula (2.8)

$$
V_t^{\text{cld}}(\varphi, A) := V_t(\varphi, A) - B_t^{0,-} \int_{(0,t]} (B_u^{0,-})^{-1} dA_u^+ + B_t^{0,+} \int_{(0,t]} (B_u^{0,+})^{-1} dA_u^-
\tag{3.2}
$$

where $A = A^+ - A^-$ is the decomposition of $A$ into its increasing and decreasing components.

In essence, we say that the hedger, who has an initial capital $x$, can produce an arbitrage opportunity using a contract $A$ if he can find an admissible strategy $\varphi$ such that the netted wealth at time $T$ is non-negative and strictly positive with a positive probability. The financial interpretation of the netted wealth at time $T$ reads as follows: the hedger who has the initial capital $x$ enters at time $0$ a given contract $A$ and assumes also the virtual opposite position in the same contract. In particular, the additional cash flow at time $0$ equals $0$, since the premia cancel out. Next, he selects a hedging strategy for the contract and, at the same time, he uses external lenders to fund cash flows associated with the opposite position. The idea underpinning the next definition is a comparison of the dynamically hedged ‘long’ position in a given contract with the corresponding ‘short’ position in which all outgoing or incoming cash flows are reinvested in unsecured accounts $B^{0,+}$ and $B^{0,-}$.

**Definition 3.1** A hedger’s arbitrage opportunity associated with a contract $A$ is any trading strategy $\varphi$ such that the discounted netted wealth process $\tilde{V}^{\text{cld}}(\varphi, A)$ is bounded from below by a constant and the following conditions are satisfied: $V_T^{\text{cld}}(\varphi, A) \geq L_T(\tilde{V}_0(\varphi))$ and $\mathbb{P}(V_T^{\text{cld}}(\varphi, A) > L_T(\tilde{V}_0(\varphi))) > 0$ where we denote $L_T(x) := x^+ B_T^{0,+} - x^- B_T^{0,-}$.

**Remark 3.2** The postulate that the discounted netted wealth process $\tilde{V}^{\text{cld}}(\varphi, A)$ is bounded from below by a constant is merely a technical condition of admissibility, which is commonly used to ensure that if the process $\tilde{V}^{\text{cld}}(\varphi, A)$ a local martingale under some probability measure then it is a supermartingale. Of course, this issue appears even in the simplest case of valuation of options in the Black and Scholes model, so it cannot be avoided when dealing with a general continuous-time framework, but it is by no means specific to the non-linear pricing examined in the present work.

**Remark 3.3** Note also that the discount factor is left here somewhat unspecified. If the constant in Definition 3.1 is set to be zero, so that the netted wealth is non-negative, it suffices to consider the netted wealth without any discounting and thus the problem of the choice of discounting in Definition 3.1 disappears. Otherwise, it will depend on the problem and model at hand (see, for instance, Proposition 3.2).
Remark 3.4 For simplicity of presentation, we do not introduce explicitly in the right-hand side of (3.2) default times, close-out payment and benefit at default. Hence this form of self-financing condition is suitable for measuring the impact of funding and collateral, but it should be slightly amended to cover the cash flows at the time of a default. A suitable extension is straightforward and it will be done in the second part of this research.

Comments. Since Definition 3.1 departs from the usual way of introducing the concept of an arbitrage opportunity, we will now make some pertinent comments. Let \( x = V_0(\varphi) \) be the initial capital of the hedger. Then the inequality \( V_{T_{\mathit{cld}}}^c(\varphi, A) > L_T(V_0(\varphi)) \) reads

\[
V_T(\varphi, A) > x^+ B_{T}^{0,+} - x^- B_{T}^{0,-} + B_{T}^{0,-} \int_{[0,T]} (B_u^{0,-})^{-1} dA_u^+ - B_{T}^{0,+} \int_{[0,T]} (B_u^{0,+})^{-1} dA_u^-
\]

and it is now clear that we are in fact comparing here the outcomes of a fully dynamic hedging with a semi-static funding based on unsecured accounts only. It is thus fair to acknowledge that Definition 3.1 is only the first step towards a more general view of arbitrage opportunities that might arise in the context of differing funding costs and credit qualities of a pool of potential counterparties.

Its natural extension would rely on a comparison of two fully dynamically hedged positions in \( A \) so that we would end up with the following condition: an arbitrage opportunity is a pair \((\varphi, \psi)\) of admissible strategies for the hedger such that \( V_0(\varphi) = V_0(\psi) \) and \( V_T(\varphi, A) - V_T(\psi, -A) \geq 0 \) and \( P(V_T(\varphi, A) - V_T(\psi, -A) > 0) > 0 \).

This more general view would mean that an arbitrage opportunity could be created by taking advantage of the presence of (at least) two potential counterparties with differing credit qualities. Needless to say that this extension would require to introduce at least one more potential counterparty, so that the minimal trading model would now include the hedger and his two counterparties. This seems to be a promising avenue for the theoretical research that could be pursued in the future. However, this extended definition would require the possibility of taking opposite positions in an OTC contract with identical features with two different counterparties and this does not seem to be a plausible postulate from the practical perspective.

The arguments in favor of Definition 3.1 can be summarized as follows: in particular cases of market models its implementation is relatively easy, it yields explicit conditions that make financial sense and, last but not least, it clarifies and justifies the use of the concept of a martingale measure in the general set-up of a market with funding costs, collateralization and defaults. To sum up, although Definition 3.1 is open to criticism, it seems to be an adequate tool to deal with the hedging and valuation issues in the current non-linear trading environment.

3.2 Arbitrage-Free Property

The concept of an arbitrage-free property can now be introduced either with respect to all contracts \( A \) that can be covered by a particular model or by selecting first a particular class \( A \) of contracts of our interest. In principle, the arbitrage-free property depends also on the initial capital \( x \) of the hedger. Recall that we denote \( L_T(x) := x^+ B_{T}^{0,+} - x^- B_{T}^{0,-} \).

Definition 3.2 We say that a market model is arbitrage-free for the hedger with respect to the class \( A \) of financial contracts whenever no arbitrage opportunity associated with any contract \( A \in A \) exists. It other words, for any self-financing strategy \( \varphi \) and any contract \( A \in A \) if the discounted netted wealth process \( V_{T_{\mathit{cld}}}^c(\varphi, A) \) is bounded from below by a constant then

\[
P(V_{T_{\mathit{cld}}}^c(\varphi, A) < L_T(V_0(\varphi))) > 0. \tag{3.3}
\]

Remark 3.5 Of course, the situation is not symmetric here, that is, a model in which no arbitrage opportunities for the hedger exist may still allows for arbitrage opportunities for the counterparty. Even when the market conditions are exactly symmetrical for both parties, the cash flows of a contract are not symmetrical and thus the prices for both parties may be different.
Remark 3.6 If we assume that $B_{0,+} = B_{0,-} = B_0$ then we obtain the following equivalent condition $P(\tilde{V}_T^{\text{cld}}(\varphi, A) < V_0(\varphi)) > 0$. If we now set $A = 0$ then the netted wealth process $V^{\text{cld}}(\varphi, 0)$ coincides with the wealth process $V(\varphi)$ and thus Definition 3.2 formally reduces to the classic definition of an arbitrage-free market. Hence our pricing method agrees with the linear arbitrage pricing theory if no frictions are present in the market model (or when they do not affect a contract at hand).

3.3 Hedger’s Arbitrage Prices

Let us assume that the market is arbitrage-free in the sense of Definition 3.2. The next step is to define the range of arbitrage prices of a contract with cash flows $A$. Let $x$ be an arbitrary initial capital of the hedger and let $p$ stand for a price of a contract at time 0 for the hedger. A positive value of $p$ means that the hedger receives the cash amount $p$ at time 0, whereas a negative value of $p$ means that he makes the payment $-p$ to the counterparty at time 0. It is clear from the next definition that the price may depend on the hedger’s initial capital $x$ and is not unique, in general.

Definition 3.3 We say that $p$ is a hedger’s price for $A$ whenever for any trading strategy $\varphi$ with the initial wealth $x + p$, and such that the discounted wealth process $\tilde{V}(\varphi, A)$ is bounded from below by a constant, we have that either

$$P(\tilde{V}_T(\varphi, A) < L_T(x)) > 0$$ \hspace{1cm} (3.4)

or

$$P(\tilde{V}_T(\varphi, A) = L_T(x)) = 1.$$ \hspace{1cm} (3.5)

The financial interpretation of condition (3.4) is that if the hedger has the initial capital $x$ and enters the contract $A$ at the price $p$ then he should not be able to construct an admissible trading strategy $\varphi$ with $V_0(\varphi) = x + p$ and such that

$$P(\tilde{V}_T(\varphi, A) \geq L_T(x)) = 1,$$

where the inequality is strict with a positive probability. In other words, the hedged position in the contract $A$ should not outperform the cash investment in all states of the world at time $T$. In practice, the initial capital $x < 0$ can be interpreted as the amount of cash borrowed by the trading desk from its internal funding desk, which should be repaid with interest $B_{0,-}^{-T}$ at time $T$. Therefore, an arbitrage opportunity would mean that the price $p$ is high enough to allow the hedger to make profits without any risk. Of course, condition (3.5) corresponds to the situation when a contract can be replicated; this special case of non-linear pricing technique through solutions to non-linear BSDEs is examined in Section 4.

3.3.1 Martingale Measures for the First Model

Our next goal is to show that the concept of a martingale measure can still be used as a tool, although it is now less clear how a martingale measure should be chosen. In this subsection, we continue the study of the market model introduced in Section 2.2. We postulate, in addition, that self-financing trading strategies $\varphi$ satisfy condition (2.14), so that equality (2.13) holds. As was already mentioned (see Remark 2.6), condition (2.14) means that repo trades are subject to the instantaneous resettlement, so that the discounted wealth equals $\tilde{V}(\varphi, A) := (B_T^{0,-})^{-1}V_T(\varphi, A)$. Since process $A$ is fixed, we skip it from the notation for $\tilde{V}$ in what follows. Then we have the following result, which closely resembles classic results for market models with a single funding account.

Proposition 3.1 Assume that there exists a probability measure $\tilde{P}$ on $(\Omega, \mathcal{G}_T)$ such that the processes $\tilde{S}_i^{\text{cld}}$, $i = 1, 2, \ldots, d$ are $(\tilde{P}, \mathcal{G})$-local martingales. Then the model of Section 2.2 is arbitrage-free.
Hence the proposition follows from the standard argument, which runs as follows: since \( \tilde{\mathbf{1}} \) under a non-negative (or bounded from below by a constant) local martingale, it is also a supermartingale.

Thus, the representation for (3.4) whereas (3.5) means that equality holds with probability one, that is,

\[ \mathbb{P}(\tilde{\mathbf{1}} = 0) = 1. \]

Annex 6.3.2

**Proof.** It suffices to observe that the discounted cumulative wealth \( \tilde{\mathbf{1}} \) satisfies

\[
\tilde{\mathbf{1}}(\varphi) = \tilde{\mathbf{1}}(\varphi) + \int_{(0,T]} (B^0_u)^{-1} dK^\varphi_u = \tilde{\mathbf{1}}(\varphi) + \sum_{i=1}^{d} \int_{(0,T]} (B^0_u)^{-1} \xi^i_u dK^\varphi_u
\]

\[
= \tilde{\mathbf{1}}(\varphi) + \sum_{i=1}^{d} \int_{(0,T]} (B^0_u)^{-1} \xi^i_u B^i_u dS^\varphi_u.
\]

Hence the proposition follows from the standard argument, which runs as follows: since \( \tilde{\mathbf{1}} \) is a non-negative (or bounded from below by a constant) local martingale, it is also a supermartingale under \( \mathbb{P} \), which in turn means that arbitrage opportunities are precluded. \( \square \)

Let us now apply definition in order to describe the set of hedger’s prices of \( A \). Recall that here \( B^0 = B^0 \), and that \( V_0(\varphi) = x + p \). After simple computations, we obtain the following representation for (3.4)

\[
\mathbb{P}(p + \sum_{i=1}^{d} \int_{(0,T]} (B^0_u)^{-1} \xi^i_u B^i_u dS^\varphi_u + \int_{(0,T]} (B^0_u)^{-1} dA_u < 0) > 0,
\]

whereas (3.5) means that equality holds with probability one, that is,

\[
\mathbb{P}(p + \sum_{i=1}^{d} \int_{(0,T]} (B^0_u)^{-1} \xi^i_u B^i_u dS^\varphi_u + \int_{(0,T]} (B^0_u)^{-1} dA_u = 0) = 1.
\]

Note that in this simple set-up the set of arbitrage prices \( p \) does not depend on the hedger’s initial wealth \( x \).

Assume that \( A_t = -X \mathbb{1}_{(t \leq T]} \) and \( B^i = B^0 \) for every \( i = 1, \ldots, d \). Then we obtain the following characterization of the set of arbitrage prices for the hedger: either

\[
\mathbb{P}(p + \sum_{i=1}^{d} \int_{(0,T]} \xi^i_u dS^\varphi_u < B_T^{-1} X) > 0
\]

or

\[
\mathbb{P}(p + \sum_{i=1}^{d} \int_{(0,T]} \xi^i_u dS^\varphi_u = B_T^{-1} X) = 1.
\]

One recognizes here the classic case, namely, the notion of an arbitrage price for the hedger as any level of a price \( p \) that does not allow for creation of a super-hedging strategy for a claim \( X \).

### 3.3.2 Martingale Measures for the Second Model

We now consider the set-up introduced in Section 2.4.3 with netting of short cash positions. We assume that \( x \geq 0 \) and we define the discounted wealth by setting \( \tilde{V}^+_i(\varphi, A) := (B^0_i)^{-1} V_i(\varphi, A) \).

**Proposition 3.2** Assume that \( r^0_i \leq r^0_i \) and \( r^0_i \leq r^i_i \) for \( i = 1, 2, \ldots, d \). Let us denote

\[
\tilde{S}^i_{t, cld} = (B^0_i)^{-1} S^i_{t} + \int_{(0,t]} (B^0_i)^{-1} dA^i_{u}.
\]

If there exists a probability measure \( \tilde{\mathbb{P}} \) on \((\Omega, \mathcal{F}_T)\) such that the processes \( \tilde{S}^i_{t, cld}, i = 1, 2, \ldots, d \) are \((\tilde{\mathbb{P}}, \mathcal{G})\)-local martingales then the model of Section 2.4.3 is arbitrage-free.
Proof. From Corollary 2.4, we know that the wealth process satisfies (see formula 2.42)

\[
dV_t(\varphi, A) = \sum_{i=1}^{k} \xi_i^t (dS_i^t + dA_i^t) - \sum_{i=1}^{d} r_i^{t-} (\xi_i^t S_i^t)^+ dt + dA_t \\
+ r_i^{0+} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^+ dt - r_i^{0-} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^- dt.
\]

Assume that \( r_i^{0+} \leq r_i^{0-} \). Then

\[
dV_t(\varphi, A) \leq \sum_{i=1}^{k} \xi_i^t (dS_i^t + dA_i^t) - \sum_{i=1}^{d} r_i^{t-} (\xi_i^t S_i^t)^+ dt + dA_t \\
+ r_i^{0+} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^+ dt - r_i^{0+} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^- dt
\]

\[
= r_i^{0+} V_t(\varphi, A) dt + \sum_{i=1}^{k} \xi_i^t (dS_i^t + dA_i^t) + dA_t - \sum_{i=1}^{d} r_i^{t-} (\xi_i^t S_i^t)^+ dt + r_i^{0+} \sum_{i=1}^{d} (\xi_i^t S_i^t)^- dt
\]

\[
\leq r_i^{0+} V_t(\varphi, A) dt + \sum_{i=1}^{k} \xi_i^t (dS_i^t - r_i^{0+} S_i^t dt + dA_i^t) + dA_t
\]

where the last inequality holds since we assumed that \( r_i^{0+} \leq r_i^{0-} \). Consequently, the discounted wealth \( \tilde{V}_t^{+}(\varphi, A) := (B_t^{0+})^{-1} V_t(\varphi, A) \) satisfies

\[
d\tilde{V}_t^{+}(\varphi, A) \leq \sum_{i=1}^{k} \xi_i^t (B_t^{0+})^{-1} (dS_i^t - r_i^{0+} S_i^t dt + dA_i^t) + (B_t^{0+})^{-1} dA_t = \sum_{i=1}^{k} \xi_i^t d\tilde{S}_i^{t,+} + (B_t^{0+})^{-1} dA_t.
\]

Furthermore,

\[
V_t^{\text{clld}}(\varphi, A) \leq V_t(\varphi, A) - B_t^{0+} \int_{(0,t]} (B_u^{0+})^{-1} dA_u
\]

and thus the netted discounted wealth \( \tilde{V}_t^{+,\text{clld}}(\varphi, A) := (B_t^{0+})^{-1} V_t^{\text{clld}}(\varphi, A) \) satisfies

\[
d\tilde{V}_t^{+,\text{clld}}(\varphi, A) \leq \sum_{i=1}^{k} \xi_i^t d\tilde{S}_i^{t,+}.
\]

The arbitrage-free property of the model now follows by the usual arguments. Specifically, the initial wealth equals \( x \geq 0 \) and thus

\[
V_T^{\text{clld}}(\varphi, A) \leq B_T^{0+} x + B_T^{0+} \sum_{i=1}^{k} \int_{0}^{T} \xi_i^t d\tilde{S}_i^{t,+}
\]

whereas \( L_T(x) = B_T^{0+} x \). Consequently, either \( V_T^{\text{clld}}(\varphi, A) < L_T(x) \) or \( \mathbb{P}(V_T^{\text{clld}}(\varphi, A) < L_T(x)) > 0 \), so that arbitrage opportunities are precluded. \( \square \)

The set of hedger’s prices \( p \) is now characterized by the following condition: either

\[
\mathbb{P} \left( x + p + \sum_{i=1}^{k} \int_{(0,T]} \xi_i^t (dS_i^t + dA_i^t) - \sum_{i=1}^{d} \int_{(0,T]} r_i^{t-} (\xi_i^t S_i^t)^+ dt + A_T - A_0 \\
+ \int_{(0,T]} r_i^{0+} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^+ dt - \int_{(0,T]} r_i^{0-} \left( V_t(\varphi, A) + \sum_{i=1}^{d} (\xi_i^t S_i^t)^- \right)^- dt < L_T(x) \right) > 0
\]

or the equality holds in the formula above with probability one.
3.4 Trading Strategies with Margin Account

Our next goal is to examine specific features related to the presence of the margin account. We denote

\[ l^+_t := \int_{(0,t]} \left( (B_{u}^{H,+})^{-1} dB_{u}^{H,+} - (B_{u}^{C,+})^{-1} dB_{u}^{C,+} \right) \]

and

\[ l^-_t := \int_{(0,t]} \left( (B_{u}^{H,-})^{-1} dB_{u}^{H,-} - (B_{u}^{C,-})^{-1} dB_{u}^{C,-} \right). \]

We place ourselves within the set-up of Section 2.2 and we consider the following two cases:

(A) the process \( C \) is independent of the hedger’s portfolio \( \varphi \),

(B) the process \( C \) depends on the hedger’s portfolio \( \varphi \).

**Case (A).** If the collateral process \( C \) is exogenously predetermined, so it is independent of the hedger’s trading strategy, then we may formally consider the process \( A^C = F^C + A \) as the full specification of a contract to be valued. In other words, it is here possible to reduce the valuation and hedging problem to the case of an unsecured contract with cash flows given by the process \( A^C \). In view of this argument, it suffices to adjust the definition of the cumulative wealth process \( V^{\text{cld}}(\varphi, A^C) \) by setting

\[ V^{\text{cld}}_t(\varphi, A^C) := V_t(\varphi, A^C) - B^0_t \int_{(0,t]} (B^0_u)^{-1} dA^C_u. \]

(3.6)

We do not need to impose here any additional restrictions on processes \( l^+ \) and \( l^- \), since it suffices to apply directly Proposition 3.1. By contrast, Proposition 3.3 is used when the collateral process depends on the hedger’s trading strategy \( \varphi \).

**Case (B).** The next goal is to extend Proposition 3.1 in order to cover the case of an arbitrary collateral process \( C \), which may possibly depend on a strategy \( \varphi \) chosen by the hedger, so that \( C = C(\varphi) \) (see, for instance, formula (2.48) in Section 2.5.2). To this end, we postulate that the processes \( l^+ \) and \( l^- \) are nonincreasing and nondecreasing, respectively. In the case of absolutely continuous processes \( B^{C,+}, B^{H,+}, B^{C,-} \) and \( B^{H,-} \), these conditions are satisfied provided that \( r^{C,+} \geq r^{H,+} \) and \( r^{H,-} \geq r^{C,-} \). Then we obtain the following expression for the dynamics of \( V^{\text{cld}}(\varphi, A) \)

\[ \bar{V}^{\text{cld}}_t(\varphi, A) = \bar{V}^{\text{cld}}_0(\varphi, A) + \sum_{i=1}^d \int_{(0,t]} (B^0_u)^{-1} \xi_u^i B^i_u d\bar{S}^i_u + \int_{(0,t]} (B^0_u)^{-1} C^+ u d\bar{S}^+ + \int_{(0,t]} (B^0_u)^{-1} C^- u d\bar{S}^- \]

**Proposition 3.3** Let us consider the model of Section 2.3 under assumption (2.14). Assume that there exists a probability measure \( \bar{P} \) on \( (\Omega, \mathcal{F}_T) \) such that \( \bar{P} \) is equivalent to \( P \) and the processes \( \bar{S}^i \), \( i = 1, 2, \ldots, d \) are \( (\bar{P}, \mathcal{G}) \)-local martingales. If, in addition, the processes \( l^+ \) and \( l^- \) are nonincreasing and nondecreasing, respectively, then the model is arbitrage-free.

Of course, an analogous result can be formulated for the model of Section 2.4.3 by extending Proposition 3.2. Let us summarize the differences between cases (A) and (B). If the collateral process \( C \) is exogenously given then the corresponding gains/losses process can be treated as a part of the hedged contract. If, however, the process \( C \) depends on \( \varphi \) then this approach is no longer valid and \( C \) should be considered as a part of the wealth process of a hedging strategy. Analogous arguments will be applied to the case of a benefit of default.

3.5 Trading Strategies with Benefits or Losses at Default

If the random amount of the benefit at default does not depend on a trading strategy then it can be formally treated as a part of the contract to be valued and hedged. Otherwise, the situation becomes more delicate and thus it is harder to handle at a general level. A similar comment applies to the concept of the loss at default.
4 Replication under Funding Costs and Collateralization

We will now apply our valuation method to the case of a contract that can be replicated. For convenience, we denote by $D$ the cumulative dividend paid by an OTC contract after its inception, as seen from the hedger’s perspective. It is assumed throughout that $D$ is a càdlàg process of finite variation with $D_0 = 0$. The cumulative dividend process accounts for all cash flows associated with a given security, such as ‘dividends’ either received or paid after time 0 and before or at the contracts maturity date $T$, including the terminal payoff $\Delta D_T$ and the close-out payoff at default.

**Example 4.1** If the the unique cash flow associated with the contract is the terminal payment occurring at time $T$, denoted as $X$, then the cumulative dividend process for this security takes form

$$D_t = X \mathbb{1}_{\{t = T\}}. \quad (4.1)$$

For instance, for the issuer of a European call option, there are no dividend payments and the terminal payoff equals $X = -(S_T - K)^+$, so that $D_t = -(S_T - K)^+ \mathbb{1}_{\{t = T\}}$.

In what follows, the prices of OTC contracts will always be defined from the perspective of a hedger. We consider throughout trading strategies satisfying condition (2.14).

**Definition 4.1** We say that a trading strategy $(\varphi, A, C)$ replicates a contract given by $D$ whenever the equality $A_t = D_t$ holds for every $t \in [0, T]$ and $V_T(\varphi) = 0$. If a contract can be replicated by a trading strategy $(\varphi, A, C)$ then the wealth $V(\varphi)$ is called the ex-dividend price associated with $\varphi$ and it is denoted $S(\varphi)$. The cum-dividend price $S^\text{cum}$ is defined as $S^\text{cum}_t(\varphi) = S_t(\varphi) - \Delta D_t$.

Note that $S_T = V_T(\varphi) = 0$ and $S^\text{cum}_T(\varphi) = V_T-(\varphi) = -\Delta D_T$. In particular, for a call option, we obtain $S^\text{cum}_T = (S_T - K)^+$.

4.1 General Valuation Results

Recall that $C = C(\varphi)$, in general. Therefore, it is not clear whether the uniqueness of the price $S(\varphi)$ holds, in the sense that if $(\varphi, A, C(\varphi))$ and $(\tilde{\varphi}, A, C(\tilde{\varphi}))$ are two replicating strategies for a given contract then necessarily $V(\varphi) = V(\tilde{\varphi})$.

4.1.1 BSDE Approach in the First Model

We consider the model previously examined in Section 3.3.1 and we work under the assumptions of Proposition 5.1. Moreover, we postulate that the collateral process $C$ is independent of a hedging strategy $\varphi$. Let us write $\tilde{E}_t(\cdot) := E_{\tilde{P}}(\cdot | \mathcal{G}_t)$ where $\tilde{P}$ is any martingale measure for the model at hand. It is assumed throughout that random variables whose conditional expectations are evaluated are integrable. For the sake of brevity, we denote $D^C = F^C + D$.

**Proposition 4.1** Assume that a derivative security $D$ can be replicated by a trading strategy $(\varphi, A, C)$. Then its ex-dividend price process $S(\varphi)$ associated with $\varphi$ equals

$$S_t(\varphi) = -B^0_t \tilde{E}_t \left( \int_{[t,T]} (B^0_u)^{-1} dD^C_u \right), \quad t \in [0, T]. \quad (4.2)$$

and the cum-dividend price satisfies

$$S^\text{cum}_t(\varphi) = -B^0_t \tilde{E}_t \left( \int_{[t,T]} (B^0_u)^{-1} dD^C_u \right), \quad t \in [0, T]. \quad (4.3)$$
Proof. Assume that \((\varphi, A, C)\) replicates \(D\). From (2.54), we obtain
\[
d\tilde{V}_t(\varphi) = \sum_{i=1}^{d} (B_0^i)^{-1} \xi_i^t dK^i_t + (B_0^i)^{-1}(dP^C_i + dD_t).
\]
(4.4)
Since \(V_T(\varphi) = 0\), this yields
\[
-\tilde{V}_t(\varphi) = \sum_{i=1}^{d} \int_{(t,T]} (B_0^i)^{-1} \xi_i^t dK^i_u + \int_{(t,T]} (B_0^i)^{-1} dD^C_u.
\]
Since processes \(K^i\) are \(\bar{P}\)-martingales, equality (4.2) follows.

To alleviate notation, we will usually write \(S\) and \(S^{\text{cum}}\) instead of \(S(\varphi)\) and \(S^{\text{cum}}(\varphi)\). The same convention will be also applied to other price processes considered in what follows. The discounted ex-dividend price process \(\bar{S}\) equals
\[
\bar{S}_t = -\bar{E}_t \left( \int_{(t,T]} (B_0^i)^{-1} dD^C_u \right), \quad t \in [0,T].
\]
(4.5)
The cumulative-dividend price is given as
\[
S_t^{\text{cum}} := S_t - B_t^0 \int_{(0,t]} (B_0^i)^{-1} dD^C_u, \quad t \in [0,T],
\]
(4.6)
and the discounted cumulative-dividend price equals
\[
\tilde{S}_t^{\text{cum}} := \tilde{S}_t - \int_{(0,t]} (B_0^i)^{-1} dD^C_u = -\bar{E}_t \left( \int_{(0,T]} (B_0^i)^{-1} dD^C_u \right), \quad t \in [0,T].
\]
(4.7)
From the formula above, it follows immediately that the discounted cumulative-dividend price \(\tilde{S}^{\text{cum}}\) is a \(\bar{G}\)-martingale under \(\bar{P}\). Let us introduce the following notation (see (2.59))
\[
K_t := S_0 + \int_{(0,t]} B_0^u d\tilde{S}_u - D^C_t = S_0 + \int_{(0,t]} B_0^u d\tilde{S}^{\text{cum}}_u,
\]
(4.8)
where the second equality follows from (1.7). It is clear that \(\tilde{S}^{\text{cum}}\) is a \(\bar{G}\)-local martingale under \(\tilde{P}\) if and only if \(K\) is a \(\bar{G}\)-local martingale under \(\bar{P}\). We refer to the martingale property of \(\tilde{S}^{\text{cum}}\) as to the multiplicative martingale property, whereas the martingale property of \(K\) is termed the additive martingale property. The integration by parts formula yields
\[
K_t = S_t - \int_{(0,t]} \tilde{S}_u dB^0_u - D^C_t, \quad t \in [0,T].
\]
(4.9)

4.1.2 BSDE Approach in the Second Model

We now proceed to the model from Section 3.3.1 and we work under the assumptions of Proposition 3.2. In particular, \(r_t^{i,+} \leq r_t^{i,-}\) and \(r_t^{i,+} \leq r_t^{i,-}\) for \(i = 1, 2, \ldots, d\). We postulate the existence of a probability measure \(\bar{P}\) on \((\Omega, \mathcal{G}_T)\) such that the processes \(\tilde{S}_t^{i,+}\), \(i = 1, 2, \ldots, d\) are \((\bar{P}, \bar{G})\)-local martingales where
\[
\tilde{S}_t^{i,+} = (B_0^{i,+})^{-1} S_t^i + \int_{(0,t]} (B_0^{i,+})^{-1} dA^i_u.
\]
Recall that the wealth process now satisfies
\[
dV_t(\varphi, A) = \sum_{i=1}^{k} \xi_i^t (dS^i_t + dA^i_t) - \sum_{i=1}^{d} r_t^{i,-}(\xi_i^t S^i_t)^+ dt + dA_t
\]
\[
+ r_t^{i,+} (V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S^i_t)^-) + dt - r_t^{i,-} (V_t(\varphi) + \sum_{i=1}^{d} (\xi_i^t S^i_t)^-) - dt.
\]
Let us consider an OTC contract with the dividend process $D$. We can now ask the following question: how to find the least expensive way of contract’s replication (or super-hedging)? More explicitly, we search for a strategy $\varphi$ satisfying $\tilde{V}_T(\varphi, D) = 0$ with the minimal initial cost. For brevity, let us represent the dynamics of $\tilde{V}(\varphi, D)$ by writing (we denote $S = (S^1, \ldots, S^d)$)

$$dV_t(\varphi, D) = \sum_{i=1}^{k} \xi_t^i (dS^i_t - r^0_{i,+} S^i_t dt + dA^i_t) + f(t, \xi_t, S_t) dt + dD_t.$$ 

Hence the discounted wealth $\tilde{V}^{0,+}(\varphi, D) := (B^{0,+})^{-1} V^{0,+}(\varphi, D)$ satisfies

$$d\tilde{V}_t(\varphi, D) = \sum_{i=1}^{k} \xi_t^i d\tilde{S}^i_{t,+} - r^0_{i,+} \tilde{V}_t(\varphi, D) dt + (B^{0,+})^{-1} f(t, \xi_t, S_t) dt + (B^{0,+})^{-1} dD_t.$$ 

Informally, our valuation problem can now be intuitively represented as the problem of finding the portion of this strategy minimizes the following expectation

$$S_0(\varphi) = -\tilde{E}\left( \int_{[0,T]} (B^{0,+})^{-1} \left( f(u, \xi_u, S_u, V_t) du + dD_u \right) \right).$$

More precisely, we search for a solution $(Z, \xi)$ to the BSDE

$$dZ_t = \sum_{i=1}^{k} \xi_t^i d\tilde{S}^i_{t,+} + (B^{0,+})^{-1} \tilde{f}(t, \xi_t, S_t, Z_t) dt + (B^{0,+})^{-1} dD_t$$

with the terminal value $Z_T = 0$ for which the initial value is minimal. One can also address the issue of finding the least expensive way of super-hedging by postulating that $Z_T \geq 0$, rather than $Z_T = 0$.

### 4.2 Piterbarg’s [29] Model

As a simple illustration of our fairly general non-linear hedging and pricing methodology, we present here a detailed study of the valuation problem previously examined by Piterbarg [29]. Following [29], we consider here three funding assets

$$B^0_t = e^{\int_t^0 r^0_u du}, \quad B^1_t = e^{\int_t^0 r^1_u du}, \quad B^C_t = e^{\int_t^0 r^C_u du}.$$ 

The spreads $r^1 - r^C$, $r^1 - r^0$, $r^C - r^0$ represent the bases between the funding rates, that is, the funding bases. For simplicity of presentation, we assume that $r^{H,+} = r^{H,-} = r^0$ and $r^{C,+} = r^{C,-} = r^C$, but no specific ordering of rates $r^0, r^1$ and $r^C$ is postulated a priori. More general situations where $r^{0,+} \neq r^{0,-}$, $r^{H,+} \neq r^{H,-}$, $r^{C,+} \neq r^{C,-}$ can also be handled using our approach.

#### 4.2.1 Arbitrage-Free Property and Martingale Measure

We assume that a stock $S^1$ pays continuously dividends at stochastic rate $\kappa$ and has the (ex-dividend) price dynamics under the real-world probability $\mathbb{P}$

$$dS^1_t = S^1_t (\mu_t dt + \sigma_t dW_t), \quad S^1_0 > 0,$$

where $W$ is a Brownian motion under $\mathbb{P}$. The corresponding dividend process $A^1$ is given by

$$A^1_t = \int_0^t \kappa_u S^1_u du.$$ 

As usual, we write $\tilde{S}^1_t = (B^1_t)^{-1} S^1_t$ and $\tilde{S}^1_{t,\text{cld}} = (B^1_t)^{-1} S^1_{t,\text{cld}}$. 

Corollary 4.1 The price process $S^1$ satisfies under $\tilde{P}$

$$dS_t^1 = S_t^1 \left( (r_t^1 - \kappa_t) dt + \sigma_t d\tilde{W}_t \right),$$

where $\tilde{W}$ is a Brownian motion under $\tilde{P}$. Equivalently, the process $\tilde{S}^{1,\text{cld}}$ satisfies

$$d\tilde{S}^{1,\text{cld}}_t = \tilde{S}^{1,\text{cld}}_t \sigma_t d\tilde{W}_t.$$  \hspace{1cm} (4.11)

The process $K^1$ satisfies

$$dK^1_t = dS^1_t - r^1_t S^1_t dt + \kappa_t S^1_t dt = S^1_t \sigma_t d\tilde{W}_t$$  \hspace{1cm} (4.12)

and thus it is a (local) martingale under $\tilde{P}$.

Proof. By the definition of a martingale measure $\tilde{P}$, the discounted cumulative-dividend price $\tilde{S}^{1,\text{cld}}$ is a $\tilde{P}$-(local) martingale. Recall that the process $\tilde{S}^{1,\text{cld}}$ is given by

$$\tilde{S}^{1,\text{cld}}_t = \tilde{S}_t^1 + \int_{(0,t]} (B_u^1)^{-1} dA_u^1, \quad t \in [0,T].$$

Consequently,

$$\tilde{S}^{1,\text{cld}}_t = \tilde{S}_t^1 + \int_{(0,t]} \kappa_u (B_u^1)^{-1} S_u^1 du = \tilde{S}_t^1 + \int_{(0,t]} \kappa_u \tilde{S}^1_u du.$$ 

Since

$$d\tilde{S}^1_t = \tilde{S}^1_t ((\mu_t - r^1_t) dt + \sigma_t dW_t),$$  \hspace{1cm} (4.13)

we obtain

$$d\tilde{S}^{1,\text{cld}}_t = d\tilde{S}^1_t + \kappa_t \tilde{S}^1_t dt = \tilde{S}^1_t ((\mu_t + \kappa_t - r^1_t) dt + \sigma_t dW_t).$$

Hence $\tilde{S}^{1,\text{cld}}$ is a $\tilde{P}$-martingale provided that the process

$$d\tilde{W}_t = dW_t + \sigma_t^{-1} (\mu_t + \kappa_t - r^1_t) dt$$  \hspace{1cm} (4.14)

is a Brownian motion under $\tilde{P}$. By combining (4.13) with (4.14) we obtain expression (4.11). Other asserted formulae now follow easily. \hfill $\square$

4.2.2 Valuation of a Collateralized Derivative Security

Exogenous collateral. Our first goal is to value and hedge a collateralized security with a bounded terminal payoff $X$ at time $T$ and a predetermined collateral process $C$. Note that here $D$ is given by formula (4.11).

To this end, we consider an admissible trading strategy $\varphi = (\xi^1, \psi^0, \psi^1, D, C)$ composed of a dividend-paying stock $S^1$, the unsecured funding account $B^0$ and the funding account $B^1$. The wealth process $V(\varphi)$ is given by

$$V_t(\varphi) := \xi_t^1 S_t^1 + \psi_t^0 B_t^0 + \psi_t^1 B_t^1$$

for every $t \in [0,T]$. We assume that $\xi_t^1 S_t^1 + \psi_t^1 B_t^1 = 0$ for every $t \in [0,T]$ (hence condition (2.14) is satisfied) so that $V_t(\varphi) = \psi_t^0 B_t^0$. Using (4.11), we obtain

$$dV_t(\varphi) = r_t^0 V_t(\varphi) dt + \xi_t^1 dK^1_t + (r_t^0 - r_t^c) C_t dt + dD_t$$  \hspace{1cm} (4.15)

where $D_t = XI_{\{t=T\}}$.

In view of (4.12) and (4.16), the discounted wealth satisfies

$$d\tilde{V}_t(\varphi) = (B_t^0)^{-1} \xi_t^1 S_t^1 \sigma_t d\tilde{W}_t + (B_t^0)^{-1} (r_t^0 - r_t^c) C_t dt + (B_t^0)^{-1} dD_t.$$  \hspace{1cm} (4.16)

Under the assumption that

$$V_T(\varphi) = 0,$$  \hspace{1cm} (4.17)

the process $V_t(\varphi)$ coincides with the ex-dividend price $S$ of the contract with the cumulative dividend $D_t = XI_{\{t=T\}}$ and collateral $C$. 
Remark 4.1 Note that (4.18) can be rewritten as follows
\[dV_t(\varphi) = \left(-r^C C_t + r^0_t(V_t(\varphi) + C_t) - r^1_t \xi^1_t S^1_t + \kappa \xi^1_t S^1_t\right)dt + \xi^1_t dS^1_t + dD_t.\]

Upon setting, \(C(t) = -C_t\), the dynamics of \(V(\varphi)\) become
\[dV_t(\varphi) = \left(r^C C(t) + r^0_t(V_t(\varphi) - C(t)) - r^1_t \xi^1_t S^1_t + \kappa \xi^1_t S^1_t\right)dt + \xi^1_t dS^1_t + dD_t.\]

This coincides with the formula derived in Piterbarg [29], although the term \(dD_t\) does not appear in [29] due to the fact that the cum-dividend wealth process is considered therein.

Consequently, the cash process \(\gamma\) (cf. Remark 2.3) satisfies
\[d\gamma_t = \left(-r^C C_t + r^0_t(V_t(\varphi) + C_t) - r^1_t \xi^1_t S^1_t + \kappa \xi^1_t S^1_t\right)dt + dD_t = \left(r^C C(t) + r^0_t(V_t(\varphi) - C(t)) - r^1_t \xi^1_t S^1_t + \kappa \xi^1_t S^1_t\right)dt + dD_t,
\]

which was already observed in Piterbarg [29] (modulo the absence of the term \(dD\) in his equation for \(d\gamma\)).

Proposition 4.2 A collateralized contract with the cumulative dividend \(D_t = X\mathbb{1}_{(t=T)}\) and the predetermined collateral process \(C\) can be replicated by an admissible trading strategy. Moreover, the ex-dividend price process satisfies, for every \(t < T\),
\[S_t = -B_t^0 \tilde{E}_t \left((B_t^0)^{-1} X + \int_t^T (B_u^0)^{-1} (r_u^0 - r^C_u)C_u du\right).\] (4.18)

Equivalently,
\[S_t = -B_t^C \tilde{E}_t \left((B_t^C)^{-1} X + \int_t^T (B_u^C)^{-1} (r_u^0 - r^C_u)(C_u + V_u(\varphi)) du\right).\] (4.19)

Proof. Formula (4.18) is an immediate consequence of (4.12). The component \(\xi^1\) of the replicating strategy is derived by noting that from (4.10), we obtain
\[-(B_t^0)^{-1} X - \int_0^T (B_t^0)^{-1} (r^0_t - r^C_t)C_t dt - V_0(\varphi) = \int_0^T \xi^1_t (B_t^0)^{-1} S^1_t \sigma_t d\tilde{W}_t.\]

Next, we set \(\psi^0_t = (B_t^0)^{-1}V_t(\varphi)\) and \(\psi^1_t = -(B_t^1)^{-1}\xi^1_t S^1_t\). To obtain (4.19), it suffices to observe that equation (4.15) can be written as
\[dV_t(\varphi) = r^C_t V_t(\varphi) dt + \xi^1_t dK^1_t + (r^0_t - r^C_t)(C_t + V_t(\varphi)) dt + dD_t\] (4.20)
and apply the same argument as above. \(\square\)

Remark 4.2 Observe that equivalence of formulae (4.18) and (4.19) indicates that the choice of discount factor can be rather arbitrary, as long as security’s (cumulative) cash flow process is appropriately modified. In case of formula (4.18) the discount factor is chosen as the price process \(B^0\) representing a traded asset, whereas in case of formula (4.19) the discount factor is chosen as the process \(B^C\), which is not even a traded asset in the present set-up. Note, in particular, that none of the two choices of the discount factor correspond to the spot martingale measure \(\mathbb{P}\) which, in the case of dividend rate \(\kappa = 0\), corresponds to the choice of \(B^1\) as the discount factor. In Section 4.3 we provide a more extensive discussion of the above observations in the context of the pricing approach adopted the paper by Pallavicini et al. [28].
Hedger's collateral. As already mentioned in Section 2.5.2, the collateral amount $C$ can be specified in terms of the mark-to-market value of a hedged security and thus, at least in theory, it can be given in terms of the wealth process $\varphi$ of a hedging strategy. For instance, it may be given as follows (see (2.48))

$$C_t(\varphi) = (1 + \delta_1^t) V^-_t(\varphi) - (1 + \delta_2^t) V^+_t(\varphi)$$

for some processes $\delta^+$ and $\delta^-$. Consequently, the discounted wealth of a self-financing strategy satisfies

$$d\tilde{V}_t(\varphi) = \xi^1_t \, dK^1_t + (B^0_t)^{-1}(r^0_t - r^C_t)(\delta^+_t V^-_t(\varphi) - \delta^-_t V^+_t(\varphi)) \, dt + (B^0_t)^{-1} dD_t. \quad (4.22)$$

We are in a position to formulate the following result.

**Proposition 4.3** The backward stochastic differential equation

$$dY_t = \xi^1_t \, S^1_t \sigma_t \, d\tilde{W}_t + (B^0_t)^{-1}(r^0_t - r^C_t)(\delta^+_t Z^-_t - \delta^-_t Z^+_t) \, dt, \quad Z_T = -X,$$

has the unique solution $(Y, \xi^1)$, where the process $Z$ satisfies

$$Z_t = -B^0_t \, \tilde{E}_t \left( (B^0_T)^{-1} X + \int_t^T (B^0_u)^{-1}(r^0_u - r^C_u)(\delta^+_u Z^-_u - \delta^-_u Z^+_u) \, du \right). \quad (4.24)$$

Then the collateralized contract with the cumulative dividend $D_t = X \mathbf{1}_{\{t = T\}}$ and the collateral process $C$ given by (4.21) can be replicated by an admissible trading strategy and the ex-dividend price $S_t(\varphi)$ equals $Z$ for every $t < T$.

**Proof.** One can prove that the price is unique, that is, it does not depend on hedging strategy. This follows from the general theory of BSDEs with Lipschitz continuous coefficients. \(\square\)

**Example 4.2** Recall that the case of the fully collateralized contract corresponds to the equality $C(\varphi) = -V(\varphi)$.

Under this assumption, we obtain

$$dV_t(\varphi) = r^C_t V_t(\varphi) \, dt + \xi^1_t \, dK^1_t + dD_t.$$ 

Consequently, assuming (1.17), we obtain the following BSDE, for $t \in [0, T]$,

$$dV_t(\varphi) = r^C_t V_t(\varphi) \, dt + \xi^1_t \, dK^1_t + dD_t, \quad V_T(\varphi) = 0.$$ 

This also means that $V_t(\varphi) = Z_t$ for all $t < T$, where $Z$ satisfies

$$dZ_t = r^C_t Z_t \, dt + \xi^1_t \, dK^1_t, \quad Z_T = -X.$$ 

The unique solution to this BSDE equals, for all $t \in [0, T]$,

$$Z_t = -B^C_t \, \tilde{E}_t((B^C_T)^{-1} X) = S_t. \quad (4.25)$$

Note that the last equality also follows immediately from (1.19). It is interesting to remark that the pricing formula (4.25) combines the expectation under the martingale measure corresponding with discounting of the stock price using the process $B^1$ with discounting of the cash flow using the process $B^C$, although it is a special case of a general formula (1.24) where cash flows are discounted using $B^0$. This illustrates the fact that the choice of a discount factor and a martingale measure, although not completely arbitrary, but subject to well known rules stemming from the Bayes formula and the Itô formula, is also to a large extent a matter of a convenient representation of the solution to the valuation problem, rather than the way of defining the price of a contract. Hence the question about the universal choice of a numéraire used for discounting of future cash flows is not well posed, although for practical purposes such a choice may be beneficial.
4.2.3 An Extension

Let us conclude this work, by making some comments on a more general version of Piterbarg’s model. Suppose that we no longer assume that the equality \( \psi_t B_t + \xi_t S_t = 0 \) holds for every \( t \in [0, T] \). From formula (2.21), we see that we need to adjust \( \hat{F}_t^C \) to

\[
\hat{F}_t^C := F_t^C - \int_0^t (r^1_u - r^0_u) (\psi_u B_u^1 + \xi_u S_u^1) \, du
\]

and thus the wealth dynamics become

\[
dV_t(\varphi) = r^0_t V_t(\varphi) \, dt + (r^1_t - r^C_t) C_t \, dt + (r^1_t - r^0_t) (\psi_t B_t^1 + \xi_t S_t^1) \, dt + \xi_t \, dK_t^1
\]

where we assume, for simplicity, that the collateral process \( C_t \) is given. Consequently, the pricing formula (4.18) for the claim \( X \) takes the following form

\[
V_t(\varphi) = B_t^0 T_t^{-1} X - \int_t^T (B_u^0)^{-1} (r^0_u - r^C_u) C_u \, du + (r^1_u - r^0_u) (\psi_u B_u^1 + \xi_u S_u^1) \, du
\]

and the replicating strategy is determined by the equality

\[
(B_t^0)^{-1} X - \int_0^T (B_u^0)^{-1} (r^0_u - r^C_u) C_u \, du - V_0(\varphi) - \int_0^T (r^0_u - r^1_u) (\psi_u B_u^1 + \xi_u S_u^1) \, du = \int_0^T \xi_t B_t^1 (B_t^0)^{-1} S_t^1 \, \bar{d} \, \sigma_t \, d\tilde{W}_t.
\]

Let us first assume that \( r^1_t > 0 \). Then condition \( \psi_t B_t^1 + \xi_t S_t^1 > 0 \) means that positions in stocks are partially funded by the unsecured account \( B^0 \). Therefore, assuming that the inequality \( r^0 > r^1 \) is satisfied, the value of the replicating portfolio will be now higher than when the hedge is done under the assumption that \( \psi_t B_t^1 + \xi_t S_t^1 = 0 \).

By contrast, the inequality \( \psi_t B_t^1 + \xi_t S_t^1 < 0 \) means that we are allowed to borrow more cash funded with the account \( B^0 \) than it is justified by the amount of stock posted as collateral. If the inequality \( r^0 > r^1 \) holds then the value of the replicating portfolio will now be lower with respect to the situation when one hedges under our standard assumption that \( \psi_t B_t^1 + \xi_t S_t^1 = 0 \).

In a general case of unrestricted hedging, one faces the problem of solving a suitable optimization problem in order to find the least expensive way of hedging – this challenging issue is left for the future research.

4.3 Pallavicini et al. [28] Approach

In Pallavicini et al. [28], the authors formally introduce the risk-free short-term interest rate as an ‘instrumental variable’ without assuming that this rate corresponds to a traded asset. Nevertheless, they start by postulating the existence of a ‘martingale measure’ associated with discounting of prices of traded assets using this virtual risk-free rate. More importantly, they also postulate that the price of any contract can be defined as the conditional expectation of ‘discounted cash flows with costs’ using this martingale measure (see formula (1) in [28]).

Of course, this valuation recipe cannot be true if applied directly to cash flows of a given contract without making first some adjustments to cash flows, in order to account for the actual funding costs, margin account, closeout, etc. For instance, to deal with the actual funding costs, the authors propose to use formula (17) in [28] as a plausible valuation tool. All formulae on pages 1–26 in [28] are definitions describing the actual or modified cash flows, rather than pricing results derived from fundamentals; we will henceforth focus on the most intriguing result from [28], namely, Theorem 4.3. As it is shown in this result, by changing the probability measure one can avoid using the risk-free rate and thus the term ‘instrumental variable’ attributed to the risk-free rate seems to be justified.
However, as we will argue below, the approach proposed in [28] is somewhat artificial, since it requires a right guess how to make a suitable cash flows adjustment. More importantly, this rather complicated method is in fact not needed at all, since it is always enough to focus directly on the right market model with the actual funding costs and do not postulate any specific shape of the ‘risk-neutral pricing formula’.

To explain the rationale behind Pallavicini et al. [28] approach, let us consider a market model with a non-dividend paying stock $S^1$ and a savings account $B^0$ such that $dB^0_t = r^0_t B^0_t \, dt$. Although dividends, margin account and closeout can also be covered by the foregoing analysis, for simplicity of presentation, we focus here on the funding costs only.

**Assumption 4.1** We assume that our model is arbitrage-free, so that the martingale measure $\mathbb{P}^*$ for the process $\tilde{S}^1 = S^1/B^0$ exists.

Let $V(\varphi)$ be the wealth of a self-financing trading strategy $\varphi = (\xi^1, \psi^0)$. The following lemma is well known.

**Lemma 4.1** The discounted wealth process $\tilde{V}(\varphi) = V(\varphi)/B^0$ satisfies the equality $d\tilde{V}_t(\varphi) = \xi^1_t \, d\tilde{S}^1_t$ and thus it is a $\mathbb{P}^*$-local martingale (or a $\mathbb{P}^*$-martingale under suitable integrability assumptions).

Let us now define a completely arbitrary process of finite variation, say $B^\gamma$, such that $dB^\gamma_t = \gamma^t B^\gamma_t \, dt$, $t \geq 0$, $B^\gamma_0 > 0$.

It is crucial to stress that it is not postulated that this process represents a traded asset (or even has anything to do with the market model at hand). Nevertheless, it still makes sense to make the following assumption.

**Assumption 4.2** There exists a probability measure $\mathbb{P}^\gamma$ such that the process $\tilde{S}^1 = S^1/B^\gamma$ is a $\mathbb{P}^\gamma$-local martingale.

In a typical market model (say, the Black-Scholes model), this assumption will be satisfied, due to Girsanov’s theorem, but it does not mean that the process $B^\gamma$ has any specific relationship to our model. When referring to results from [28], we will sometimes interpret $\gamma$ as a virtual ‘risk-free rate’, but this interpretation is completely arbitrary and it does not have any bearing on the validity of results presented below. We now define an auxiliary process $V^\gamma(\varphi)$ associated with an arbitrary self-financing trading strategy $\varphi$.

**Definition 4.2** Let $\varphi$ be a self-financing trading strategy with the wealth process $V(\varphi)$. Then the process $V^\gamma(\varphi)$ is defined by the following formula

$$V^\gamma_t(\varphi) := V_t(\varphi) + B^\gamma_t \int_0^t (\gamma_u - r^0_u) \psi^0_u B^0_u (B^\gamma_u)^{-1} \, du. \quad (4.27)$$

Of course, the process $V^\gamma_t(\varphi)$ does not represent the wealth of a self-financing strategy, in general.

**Remark 4.3** The process $V^\gamma(\varphi)$ can be equivalently defined by

$$V^\gamma_t(\varphi) := V_t(\varphi) + B^\gamma_t \int_0^t (\gamma_u - r^0_u) (V_u(\varphi) - \xi^1_u \tilde{S}^1_u) (B^\gamma_u)^{-1} \, du. \quad (4.28)$$

Unless $\gamma$ is interpreted as the risk-free rate, no financial interpretation of the last term in the formula above is available.
Let us define the process \( \tilde{V}^\gamma(\varphi) \) by setting \( \tilde{V}^\gamma(\varphi) = V^\gamma(\varphi)/B^\gamma \). The following proposition shows that, for any self-financing trading strategy \( \varphi \), the process \( \tilde{V}^\gamma(\varphi) \) enjoys the martingale property under the probability measure \( \mathbb{P}^\gamma \). This is a purely mathematical result and it does not mean that \( \mathbb{P}^\gamma \) is a ‘risk-neutral probability’ in any sense, in general.

**Lemma 4.2** Let \( \varphi \) be a self-financing trading strategy and let the process \( V^\gamma(\varphi) \) be given by \( \ref{4.28} \). Then the process \( \tilde{V}^\gamma(\varphi) \) is a \( \mathbb{P}^\gamma \)-local martingale.

**Proof.** For the sake of brevity, we drop \( \varphi \) from the notation \( V(\varphi) \) and \( V^\gamma(\varphi) \). It suffices to show that

\[
dV_t^\gamma = \xi_t^1 \, dS_t^1
\]

or, equivalently,

\[
dV_t^\gamma - \gamma_t V_t^\gamma \, dt = \xi_t^1 \left( dS_t^1 - \gamma_t S_t^1 \, dt \right).
\]

By applying the Itô formula to \( \ref{4.28} \), we get

\[
dV_t^\gamma = dV_t + (\gamma_t - r_t^0) \psi_t^0 B_t^0 \, dt + \frac{V_t^\gamma - V_t}{B_t^0} \, dB_t^\gamma
\]

or, equivalently,

\[
dV_t^\gamma = dV_t + (\gamma_t - r_t^0)(V_t - \xi_t^1 S_t^1) \, dt + \gamma_t (V_t^\gamma - V_t) \, dt.
\]

Therefore, using the self-financing property of \( \varphi \), we obtain

\[
dV_t^\gamma - \gamma_t V_t^\gamma \, dt = dV_t - r_t^0 V_t \, dt - (\gamma_t - r_t^0) \xi_t^1 S_t^1 \, dt
\]

\[
= dV_t - r_t^0 (\xi_t^1 S_t^1 + \psi_t^0 B_t^0) \, dt - (\gamma_t - r_t^0) \xi_t^1 S_t^1 \, dt
\]

\[
= dV_t - r_t^0 \psi_t^0 B_t^0 \, dt - \gamma_t \xi_t^1 S_t^1 \, dt
\]

\[
= \xi_t^1 \left( dS_t + \psi_t^0 dB_t^0 + r_t^0 \psi_t^0 B_t^0 \, dt - \gamma_t \xi_t^1 S_t^1 \, dt \right)
\]

\[
= \xi_t^1 \left( dS_t^1 - \gamma_t S_t^1 \, dt \right)
\]

as was required to show. \( \square \)

Of course, when the equality \( \gamma = r^0 \) holds then Lemma 4.2 reduces to Lemma 4.1. Lemma 4.2 can thus be seen as an extension of Lemma 4.1 to the general case when the discount factor is not necessarily a traded asset. In the final step, we will illustrate Theorem 4.3 in \( \ref{28} \). Note, however, that a counterpart of formula \( \ref{4.31} \) is postulated in \( \ref{28} \), whereas we derive it from fundamentals.

**Assumption 4.3** Assume that a contract has a single cash flow \( X \) at time \( T \) and a replicating self-financing strategy \( \varphi \) for \( X \) exists.

Under suitable integrability assumption, the discounted wealth process \( \bar{V}(\varphi) \) of a replicating strategy is a \( \mathbb{P}^\gamma \)-martingale. Consequently, the arbitrage price of \( X \) can be computed using the risk-neutral valuation formula, specifically,

\[
\pi_t(X) = \mathbb{E}_{\mathbb{P}^\gamma}(X B_t^0 (B_T^\gamma)^{-1} | \mathcal{F}_t).
\]

Let us now take any process \( B^\gamma \) such that the probability measure \( \mathbb{P}^\gamma \) is well defined. From Proposition \( \ref{4.2} \) we deduce the following corollary showing that \( \mathbb{P}^\gamma \) can also be used as a ‘pricing measure’ after suitable adjustments of cash flows.

**Corollary 4.2** If Assumptions \( \ref{4.1}, \ref{4.2}, \ref{4.3} \) are satisfied then the price \( \pi_t(X) = V_t(\varphi) \) is also given by the following formula

\[
\pi_t(X) = \mathbb{E}_{\mathbb{P}^\gamma}(X B_t^0 (B_T^\gamma)^{-1} + B_t^\gamma \int_t^T (\gamma_u - r_u^0) \psi_u B_u^0 (B_u^\gamma)^{-1} \, du | \mathcal{F}_t).
\]

(4.31)
Since
\[
\psi_u B_u^0 = V_u(\varphi) - \xi_u S_u^1 = \pi_u(X) - \xi_u S_u^1,
\]
formula (4.31) can also be rewritten as follows
\[
\pi_t(X) = \mathbb{E}_P \left( X B_{\gamma} (B_{\gamma} T)^{-1} + B_{\gamma}^T \int_t^T (\gamma_u - r^0_u) (\pi_u(X) - \xi_u S_u^1) (B_{\gamma}^u)^{-1} du \bigg| \mathcal{F}_t \right).
\]

Proof. It suffices to show that the right-hand side in (4.31) coincides with \( V(\varphi) \) where a strategy \( \varphi \) replicates \( X \). The martingale property of \( \bar{V}_\gamma(\varphi) \) under \( \mathbb{P} \gamma \) means that, for all \( t \in [0, T] \),
\[
\bar{V}_\gamma^\gamma(\varphi) = \mathbb{E}_{\mathbb{P} \gamma} \left( \bar{V}_\gamma^\gamma(\varphi) \big| \mathcal{F}_t \right).
\]
In view of (4.28) and the equality \( V_T(\varphi) = X \), equality (4.33) implies that
\[
\bar{V}_\gamma^\gamma(\varphi) = \mathbb{E}_{\mathbb{P} \gamma} \left( \bar{V}_\gamma^\gamma(\varphi) \big| \mathcal{F}_t \right).
\]
This immediately yields the asserted formula. \( \square \)

As was already mentioned, a version of formula (4.32) was postulated in [28] as a valid valuation recipe under funding costs (see the first formula in Section 4.5.1 in [28]). In our opinion, the arguments put forward in [28], although they sometimes lead to a correct valuation result, are too complicated and they may require some guesswork for finding the adjustment of cash flows. It is much simpler, as it appears, to start with a market model in which ‘instrumental variable’ (e.g., a non-traded risk-free short-term rate) is not employed at all. Needless to say that formula (4.30) is much easier to establish and implement than (4.32), so there is no practical advantage of using the latter representation for the numerical pricing purposes.
