Abstract

The quasi-static strain (QSS) is the product induced by the lattice thermal expansion after ultrafast photo-excitation. Although the QSS and thermal effects are barely distinguishable in time, they should be treated separately because of their different fundamental actions to ultrafast spin dynamics. By employing ultrafast Sagnac interferometry and the magneto-optical Kerr effect, we demonstrate quantitatively the existence of QSS and the decoupling of two effects counteracting each other in typical polycrystalline Co and Ni films. The Landau-Lifshitz-Gilbert and Kittel equations considering a magnetoelastic energy term showed that QSS, rather than the thermal energy, in ferromagnets plays a governing role in ultrafast spin dynamics. This demonstration provides an essential way to analyze ultrafast photo-induced phenomena.

*Email: hwoarang@kunsan.ac.kr
Magnetoelasticity, which is the coupling of spin and strain, is a universal phenomenon in magnetic materials and enables active control of the spin states by modifying the material dimensions\(^1\). Thus far, it has been investigated that the spin dynamics after ultrafast spin angular momentum transfer by photo-excitation\(^2-7\) is governed by time-dependent effective fields with origins, such as magnetocrystalline\(^8\), dipole, Zeeman\(^9\), exchange\(^10-12\), terahertz\(^13,14\), magnetoelasticity\(^15,16\), and spin current\(^17-19\). These have been described mainly by electron and spin degrees of freedoms, while the lattice degree of freedom was highlighted only recently\(^20\).

The increase in lattice temperature by photo-excitation generates two types of strain, which are the propagating strain \(\eta_p(z, t)\) with a few-ps temporal width and the QSS \((\eta_{qss}(t))\) near a surface with a long decay time. In the recent decade, the interaction of spins with \(\eta_p\) has attracted considerable research attention from diverse points of view\(^21-23\). On the other hand, QSS has not been a major focus despite its comparable amplitude to that of \(\eta_p\). As principal reasons, the QSS and thermal dependence of materials are inextricable, particularly in photo-induced experiments. Moreover, the QSS is difficult to quantify only with a differential reflectivity that is typical measurement data in a pump-probe experiment. Therefore, great care should have been taken in determining \(\eta_{qss}(t)\). In general, the three temperatures model is used to extract the time-dependent temperature information of the sub-systems by fitting with the experimental curves of spin and reflectivity dynamics. On the other hand, the model does not reflect the strain effect that exists in the reflectivity provided the thermal expansion does. This might deliver improper messages and hinder unveiling the new physics of ultrafast dynamics. The earlier work describes the contributions of coherent (QSS) and noncoherent phonons (thermal) to the spin dynamics of a galfenol film depending on the external magnetic field strength\(^24\). In addition, for an integrated understanding, the experimental quantification of the QSS and its competition with the thermal effect by various experimental conditions remain to be proven. As the QSS and the thermal effects have different contributions to dynamics (the former changes the plasmonic\(^25\) or electronic bands\(^26\) and the latter changes the electron populations), systematic and comprehensive measurement
approaches to separate the two effects are required for the complete analysis on the fundamental mechanism of the ultrafast photo-induced spin dynamics.

Using ultrafast Sagnac interferometry (USI) and a magneto-optical Kerr effect (MOKE) instrument, we demonstrated that the QSS in ferromagnetic films governs the ultrafast spin dynamics from the first ps to the ns timescale. In particular, USI was used to prove the existence of QSS by measuring the lattice expansion dynamics directly. Here, three important sets of evidence that could not be explained by the thermal effect are as follows: i) the increase in spin precession frequency with the pump intensity, ii) $\pi$-phase inversion of the precession, and iii) the pronounced background distinguished from incoherent phonons and magnons. The model calculation of the Landau-Lifshitz-Gilbert (LLG) equation incorporating the time-dependent QSS strongly supports that all features mentioned are elucidated by one concept of QSS. The scenario was consolidated with full consistency using other ferromagnets (Co, Ni, and Ni$_x$Fe$_{1-x}$) to adjust the competition between strain and thermal effects.

**Results**

**Experimental geometry and USI measurement.** The measurement geometries are shown in Fig. 1a. The bilayer of Al$_2$O$_3$(5 nm)/Co(25 nm)/Al$_2$O$_3$ and the trilayer of Co(200 nm)/Al$_2$O$_3$(15 nm)/Co(25 nm)/Al$_2$O$_3$ were prepared by magnetron sputtering (nm in thickness are omitted hereafter). The Al$_2$O$_3$ was deposited in the bilayer to prevent oxidation. The trilayer was used for acoustic impedance matching with Co and to suppress the possible propagation of thermal magnons from the top Co layer. We used Ti:sapphire regenerative amplified laser pulses with a repetition rate of 10 kHz, a temporal width of 40 fs, and a center wavelength of 800 nm (The details of the MOKE setup are given in Methods). For MOKE measurements, the frequency-doubled pump pulses ($\lambda_{pu} = 400$ nm) excite the front sides of samples and probe pulses ($\lambda_{pr} = 800$ nm) measure the differential Kerr rotation $\Delta \theta(t)$ and
reflectivity $\Delta R(t)$ either of the front side for the bilayer or the back side for the trilayer, as shown in left and middle of Fig. 1a, respectively. The strain pulse generated in the Co(200) surface in the trilayer propagates and triggers the spin precession in Co(25) layer through magnetoelastic coupling. For USI measurement, the pump pulses excite the back side of Co, and the probe pulses measure the front side (right of Fig. 1a). Figure 1b presents the simulated overall strain profile $\eta(z, t)$ for an infinite Co slab, showing both $\eta_p(z, t)$ propagating into the film depth and $\eta_{qss}(t) (= \eta(0, t))$ near the film surface with a long decay time.

The main purpose of USI built with a Ti:sapphire oscillator system\textsuperscript{27} is to measure unambiguously the lattice displacement dynamics $u(z = 0, t)$ and extract $\eta_{qss}(t)$ in the end (see Methods and Supplementary Note1 for more details of the USI instrument). Although $\Delta R(t)$ resulted from a change in a complex refractive index $n$ is linked to $\eta(z, t)$ through the relation
\[
\Delta n = \frac{\partial \eta}{\partial T} \Delta T + \frac{\partial \eta}{\partial \eta} \Delta \eta, 
\]
it is relatively difficult to extract $\eta(z, t)$ directly because of an unknown piezo-optic property ($\frac{\partial \eta}{\partial \eta}$) of materials except for Ni, Cr, and Au at specified wavelengths\textsuperscript{28,29}. Instead, as a circumvention, $\eta_{qss}(t)$ was obtained without introducing unknown coefficients by solving the one-dimensional wave equation incorporating the lattice temperature profile used as a driving source (see the strain calculation and parameter values in Methods for more details). The lattice temperature profile was calculated using a three temperatures model with proper parameter values for a bulk Co. In addition, the pump intensity calibration between the two different instruments (MOKE and USI) was performed by matching their signal levels of $\Delta R(t)/R$. Figure 1c shows the real part ($\rho = \Delta R/2R$: upper panel) and the converted lattice displacement ($u(0, t) = \frac{\lambda_{pr}}{4\pi} \delta \phi$: bottom panel) from the imaginary part ($\delta \phi$) of $\delta r/r = \rho + i \delta \phi$ (blue circles for the measurement and the yellow line for the reproduction from the calculation). Here, $r$ is defined as the complex amplitude-reflection coefficient of the sample; $\rho$ the relative change in reflectance, and $\delta \phi$ the phase change induced by the pump pulse. Then, $\eta_{qss}$, the measurement-based quantity was extracted using the relation,
\[
u(0, t) = \int_{z=0}^{d} \eta(z', t) dz', 
\]as plotted in Fig.
1d. The positive value of $\eta_{qss}$ stands for a tensile strain resulted from the lattice expansion by a sign convention.

In contrast to the reproduced yellow curve in Fig. 1c, the experimental data $u(0, t)$ shows a sharp positive peak at the first ps, indicating lattice contraction into the film direction. This may be explained by several possible candidates, such as the electronic stress\textsuperscript{30}, the magnetoelastic stress induced by demagnetization\textsuperscript{31,32}, and the lateral expansion of the lattice\textsuperscript{32,33}, which are actively in discussion. However, identifying the origin is beyond the current scope of this paper, and the lattice contraction has not been considered in the reproduction process.

**Variation of spin precession frequency as a function of pump intensity.** The solid circles in Fig. 2a show $\Delta \theta(t)$ of the Co bilayer under $H_{ext} = 0.4$ T and $\varphi = 60^\circ$ ($\varphi$: the magnetic field angle from out-of-plane direction) with various pump intensities $I_p$. The experimental curves for other field angles ($\varphi = 15, 30,$ and $45^\circ$) are presented in Supplementary Note2. The precession frequency $f$ was obtained by fitting the experimental curves with the following damped sinusoidal function:

$$\Delta \theta(t) = A \exp(-\frac{t}{\tau_1}) \sin(2\pi ft + \delta_0) + B \exp(-\frac{t}{\tau_2}) + C,$$

where $\tau_1$ is the spin relaxation time, $\tau_2$ the decay time of the background signal, $\delta_0$ the initial phase of the precession, $A$ and $B$ are the amplitudes of the first two terms in the right-hand side, and $C$ is defined as the background offset. The solid line in Fig. 2a denotes the fit curve for the highest $I_p$. Figure 2b shows that the change in the precession frequency ($\Delta f/f_m = (f-f_m)/f_m$) increases with $I_p$ for all magnetic field angles ($\varphi = 15^\circ$: black, $30^\circ$: red, $45^\circ$: green, $60^\circ$: blue circles). Here, $f_m$ is defined as the precession frequency for the minimum $I_p$ and corresponds to 13.8, 20.0, 24.4, and 27.6 GHz for the respective angles of $\varphi$ (15, 30, 45, and 60 $^\circ$). This frequency variation observed for the polycrystalline Co film has an opposite trend to what would be expected from the conventional magnetic energy terms.
of the magneto-crystalline, dipolar, and Zeeman energy. The magnitude of the effective magnetic field \( H_{\text{eff}}(t) \) in such case would decrease with increasing temperature of the sub-systems or the increase of \( I_p \).

In order to figure out the effect of \( \eta_{\text{qss}}(t) \) on the precession frequency \( f \), we solved the following LLG equation.

\[
\frac{d\mathbf{M}}{dt} = -\gamma_s \mu_0 (\mathbf{M} \times \dot{\mathbf{H}}_{\text{eff}}) + \frac{\alpha_d}{M_s} (\mathbf{M} \times \frac{d\mathbf{M}}{dt}),
\]

where \( M_s \) is the saturation magnetization, \( \dot{\mathbf{H}}_{\text{eff}} \) the effective magnetic field vector defined as \( \dot{\mathbf{H}}_{\text{eff}} = -\partial F_{\text{tot}} / \mu_0 \partial \mathbf{M} \), \( \gamma_s = 1.63 \times 10^{11} \text{ rad/s-T} \) the gyromagnetic ratio, \( \alpha_d = 0.015 \) is assumed. The total magnetic free energy (\( F_{\text{tot}} \)) consists of the magnetocrystalline, dipole, Zeeman, and the magnetoelastic energy terms as follows:

\[
F_{\text{tot}} = K_u (\mathbf{M}) \sin^2 \vartheta + \frac{1}{2} \mu_0 \sum_i N_i M_i^2(t) - \mu_0 \sum_i M_i(t) H_{\text{ext},i} - \frac{3}{2} \lambda_s \sigma_s \cos^2 \vartheta.
\]

For the polycrystalline Co film, we used following parameter values: uniaxial magnetic anisotropy coefficient \( K_u \sim 0 \), the magnetostriction value \( \lambda_s = -62 \text{ \mu} \), the mechanical stress \( \sigma_s = 3(1 + \nu)(1 - \nu) \) \( \lambda \eta_{\text{qss}}(t) \), Poisson’s ratio \( \nu = 0.31 \), the bulk modulus \( B = 190 \text{ GPa} \), and the demagnetizing factor \( N_x = N_y = 0, N_z = 1 \). \( \vartheta \) is defined as the angle between the magnetization \( \mathbf{M} \) and \( \sigma_s \) (out-of-plane) direction.

After calculating the spin precession and extracting \( f \), the simulation results are summarized in Fig. 2c. The values of \( \Delta f/M \) considering \( \eta_{\text{qss}}(t) \) (solid lines, on the left axis) are in good agreement with experimental data of Fig. 2b, showing an increase in \( \Delta f/M \) up to 2% for a wide range of \( \varphi \). In contrast, for the absence of \( \eta_{\text{qss}}(t) \), \( \Delta f/M \) decreased by 1.6% (dashed lines, on the right axis), as expected with conventional energy terms. We also checked the case when the spin precession was involved in neither thermal nor QSS effects. This requirement was met by the back-side measurement of the trilayer
structure. The strain pulse $\eta_p(\tau, t)$ generated from the Co top layer propagates to the Co underlayer without carrying the thermal energy and contributes only to triggering spin precession through magnetoelastic coupling. From $\Delta \theta(t)$ with a function of $I_p$ under $\phi = 60^\circ$ in Fig. 2d (the fit curve with Eq. (1) for the highest $I_p$ is denoted by the solid line), $\Delta f/f_m$ did not show a noticeable change within the experimental uncertainty (the pink curve in Fig. 2b). Here, $I_p = 2.6 \text{ mJ/cm}^2$ corresponds to $\sim 70\%$ of the burning threshold for the Co top layer.

**Ferromagnetic resonance frequency dependence on $T$, $\phi$, and $\eta_{qss}$.** To obtain the comprehensive picture of the QSS effect on $f$ over a wide range of temperature and field angle, the ferromagnetic resonance frequency $f_r$ was calculated using the classical Kittel equation with the magnetic free energy $F$, as used in the dynamics case.

$$f_r = \frac{\gamma_s (F_{sz} F_{sz} - F_{sz}^2)^{1/2}}{2\pi M(T) \sin \zeta_{eq}}, \quad (4)$$

where $F_{pq} = \frac{\partial^3 F}{\partial p \partial q}$. The symbols $\zeta$ and $\xi$ denote the polar and azimuthal angles in a spherical coordinate system, respectively. $\zeta_{eq}$ is defined as the equilibrium angle of magnetization, and $\xi = \pi/2$ is set due to the azimuthal symmetry of the sample. As the classical Kittel equation generally treats the static regime, the QSS is assumed to be a constant supposing no thermal relaxation after a thermal equilibrium among the sub-systems. Hence, the QSS can be handled simply with thermal strain $\eta_{th}(T) = \beta \Delta T$ (thermal expansion coefficient of Co$^{36}$: $\beta = 13.7 \mu$). Figures 3a and b present the contour map of $f_r$ with the control parameters of $T$ (x-axis) and $\phi$ (y-axis) under $H_{ext} = 0.4$ T in the absence and presence of $\eta_{th}(T)$, respectively. Fig. 3a shows that $f_r$ decreases monotonically with increasing $T$ at a fixed value of $\phi$ (along the yellow line). In contrast, Fig. 3b indicates that $f_r$ increases gently with $T$ up to $\sim 800$ K (blue box region). This is because $\eta_{th}(T)$ increases almost linearly.
with $T$, unlike the barely altered $M(T)$ owing to its high Curie temperature $T_c$. Hence, the effect of magnetoelasticity plays a dominant role over those of the conventional magnetic energy terms. At a higher $T$ (orange box region), the rapid drop of $M(T)$ reduces the effective field strength, leading to the inflection point of $f_i$ around 800 K.

This is not a special case only for Co but can be generalized to a broad class of magnetoelastic materials. We can expect that for low $T_c$ materials, a faster decrease of $M(T)$ shows up at a lower $T$ or $I_p$, where the QSS effect on $f_i$ is comparatively weaker. The Ni can be a good tester to examine the competition of the thermal and strain effects. The Ni has a low $T_c = 630$ K and $M = 525$ emu/cm$^3$, which are the key parameters for the thermal effect but similar $\lambda$, $\beta$, and $B$ values to Co, which are related to the strain effect. Fig. 3c shows the contour map of $f_i$, including the QSS effect for Ni, and Fig. 3d presents $\Delta f_{f_m}$ for $\varphi = 25, 45, \text{ and } 60 \degree$ selected from the contour map. In contrast to the Co case, $f_i$ decreases first at a low $T$, meaning that the thermal effect is dominant, and is switched to the increase with increasing $T$. To prove those results experimentally, $\Delta \theta(t)$ of Ni(270)/SiO$_2$ at $\varphi = 25$ $\degree$ and $I_p \leq 2.2$ mJ/cm$^2$ was measured and plotted in Fig. 3e. As presented in the inset, after fitting the data with Eq. (1) (denoted as the solid line for the highest $I_p$), $\Delta f_{f_m}$ becomes first negative and then positive as $I_p$ increases. These curves reproduce the calculation (Fig. 3d) in excellent agreement supporting our analysis on thermal and QSS effects.

**Governing role of QSS on ultrafast spin dynamics.** We address that the QSS has a decisive role in determining the initial status of spin dynamics judged by further features that have been underrated. The first point is the phase of the spin precession. Figure 4a presents the calculated curves of $\Delta M_z(t)/M_z$ in the absence (red) and presence (blue curve) of $\eta_{qss}(z, t)$ under $H_{\text{ext}} = 0.54$ T and $\varphi = 60 \degree$. Here, the spin precessions in Co and Ni (Fig. 2a and 3e) correspond to the blue curve, leading to a $\pi$-phase inversion compared to conventional free energy analysis.
The pictorial description of the inset explains the \( \pi \)-phase difference concisely. According to conventional energy analysis, the sudden decrease in \( M(t) \) after photo-excitation results in a rotation of \( H_{\text{eff}}(t) \) (yellow solid arrow) to the out-of-plane direction \( (H'_{\text{eff}}(t) \) - red dashed arrow) due mainly to the decrease in dipolar energy (for polycrystalline or isotropic materials) and starts precessing around the new axis \( H'_{\text{eff}}(t) \). This aspect takes place when the thermal effect dominates the QSS effect for such conditions of \( \lambda_s \eta_{\text{qss}} \geq 0 \) \( (\lambda_s \geq 0, \beta \geq 0 \) and \( \lambda_s \leq 0, \beta \leq 0 \) and even \( \lambda_s \eta_{\text{qss}} \leq 0 \) \( (\lambda_s \leq 0, \beta \geq 0 \) provided the magnitude of \( \lambda_s \) is small. On the other hand, for \( \lambda_s \eta_{\text{qss}} \ll 0 \), the QSS effect prevails over the thermal effect and drives the rotation of \( H_{\text{eff}}(t) \) towards the in-plane direction \( (H''_{\text{eff}}(t) \) - blue dashed arrow). The spins start the precession around the \( H''_{\text{eff}}(t) \) axis. This orientation is determined at the initial stage of the precession, immediately after demagnetization. \( \text{Ni}_{x}\text{Fe}_{1-x}(180)/\text{Al}_2\text{O}_3 \) films were tested experimentally to verify this scenario, as plotted in Fig. 4b. As the alloys of \( x \approx 0.36 \) and 0.8 have negligible \( \beta \) and \( \lambda_s \) values, respectively, it is expected that they have low magnetoelastic energy \( (\propto \lambda_s \beta \Delta T) \). These cases rotate \( H_{\text{eff}}(t) \) towards \( H''_{\text{eff}}(t) \), inducing negative values at the first half period (20 ~ 30 ps), as the conventional analysis does, as shown with the red graph in Fig. 4a.

The second feature is the pronounced decaying background (yellow dashed line in Fig. 4a). This in general has been considered as incoherent thermal phonons and magnons with nonzero wavenumbers\(^{37}\), which have the heat dissipation timescale. Rather, our analysis suggests that this needs to be interpreted as the contribution of coherent rotation of \( H_{\text{eff}}(t) \) because of the QSS effect. This was clearly verified from the fact that Co and Ni with high magnetoelastic energy have much larger decaying offsets than those of NiFe alloys. These all features mentioned above, including the frequency increase in the spin precession, are reproduced through the model calculation incorporating only one concept of the QSS effect with the full consistency with the experimental data.

**Discussion**

By decoupling the thermal and the quasi-static strain effects using ultrafast Sagnac interferometry and
the magneto-optical Kerr effect, we proved that the quasi-static strain has a governing role over the thermal effect on the overall behavior of ultrafast spin dynamics over a wide range of time scales. The ultrafast photo-excitation can strengthen the effective magnetic field due to the quasi-static strain effect. This leads to a higher frequency of spin precession and accounts for the $\pi$-phase inversion determined from the initial stage of the precession. Besides, the long-lived offset with the relaxation timescale of the quasi-static strain was interpreted as extra gain induced by the contribution of a coherent rotation of $H_{\text{eff}}(t)$. This study shows that the quasi-static strain is involved universally in a wide family of magnetoelastic materials and should be treated fundamentally.

The strain of $0.1 \sim 1$ % generated by photo-excitation is high enough to induce the modification of the electronic band structure$^{26}$ even at ultrafast time scales$^{38}$. Therefore, it can be predicted that the quasi-static strain modifies the dielectric tensors, bringing about new features, such as derivative-like changes in differential magneto-optics, leading to inequivalence between its real and imaginary parts and differential reflectivity as well acting as involuntary extra gains, even after thermal equilibrium timescale. To date, considerable effort has been made to identify genuine magnetism and the origin of demagnetization$^{3,20,39-45}$. Our demonstration that the quasi-static strain governs the spin dynamics is the clear-cut result toward a new perspective in interpreting ultrafast magneto-optics. This work makes a significant advance by considering both strain and thermal effects for better understanding the physical mechanisms behind the ultrafast phenomena.
Methods

**Time-resolved pump-probe MOKE.** We used Ti:sapphire regenerative amplified laser pulses with a repetition rate of 10 kHz, a temporal width of 40 fs, and a center wavelength of 800 nm. The pump pulses are frequency-doubled with a beta Barium Borate (BBO) crystal and have a temporal width of 60 fs at a sample position. The pump and probe pulses were focused on the sample with diameter sizes of 150 μm and 30 μm, respectively, and their intensity ratio was set to ~1000:1. The reflected probe pulses from the samples were split into orthogonal polarizations using a Wollaston prism and analyzed into the differential Kerr rotation $\Delta \theta(t)$ and differential reflectivity $\Delta R(t)$. An external magnetic field of $H_{\text{ext}} = 0.4$ T was applied with various angles $\varphi$ from the normal to the sample plane.

**Ultrafast Sagnac interferometer.** An ultrafast Sagnac interferometer based on a Ti:sapphire oscillator system issued with a center wavelength of 800 nm and a temporal width of 40 fs was employed to obtain a quantitative profile of the time-resolved lattice thermal expansion after the pump excitation. After passing through an electro-optic modulator operating at 1 MHz, the dispersed pulse was compressed to 45 fs by pairs of negative-chirped mirrors. The pump pulses were frequency-doubled by a 500-μm-thick BiB$_3$O$_6$ (BiBO) crystal with a conversion efficiency of 25 % and had a temporal width of 65 fs at a sample position. The probe and pump pulses were focused on the front and back sides of the samples in normal incidence. The numerical apertures of the objective lenses used in each beam line were 0.55 and 0.4, respectively. The temporal delay between p-pol. (arrives at a negative delay) and s-pol. probes (arrives at a positive delay) at the sample position were fixed to ~1 ns and the s-pol. probes measure the pump-induced optical responses ($\rho$ and $\delta \phi$) (Supplementary Note1 for more details of the setup schematics and characteristics).

**Strain calculation and parameter values.** To obtain $\eta(z, t)$, it is necessary to solve the three temperatures model and one-dimensional wave equation in the Co(25)/Al$_2$O$_3$ structure. The three temperatures model (Eq. (5)) is described as follows:
\[ C_i(T_i) \frac{\partial T_i}{\partial t} = \delta \kappa \left[ \frac{\partial}{\partial z} \left( \kappa \frac{\partial T_i}{\partial z} \right) + P(z, t) \right] - g_{ij} \Delta T_j, \quad (5) \]

where \( i, j = e, l, s \) stand for electrons, lattice, and spins, respectively. The \( C_i \) and \( \kappa \) are the heat capacity per unit volume of bath \( i \) and the thermal conductivity. The \( g_{ij} \) is the coupling coefficient between two baths \( i \) and \( j \), and \( P(z, t) \) the laser source term. Using boundary conditions – continuities of both the heat transfer at air/Co \( \left( \frac{\partial T_i}{\partial z} \right)_{z=0, Co} \), Co/Al\(_2\)O\(_3\) \( \left( \frac{\partial T_i}{\partial z} \right)_{z=d, Co} = \kappa_{Al2O3} \left( \frac{\partial T_i}{\partial z} \right)_{z=d, Al2O3} \) and the temperatures at Co/Al\(_2\)O\(_3\) \( (T_i(z, t)\big|_{z=d, Co} = T_{Al2O3}(z, t)\big|_{z=d, Al2O3}) \)– temperature profiles of the three baths were obtained.

Here, since there is an arbitrariness for the selection of pump intensity and unknown value of \( C_s \), we carefully chose the value by matching with the experimental data of both \( u(z = 0, t) \) of the Sagnac measurement and the demagnetization \( \Delta \theta_L(t)/\theta_L \) (longitudinal geometry) under \( H_{ext} = 0.5 \text{ T} \) and \( \varphi = 90^\circ \). That is, \( T_l(z, t) \) obtained from three temperatures model calculation (Eq. (5)) is linked \( u(z, t) \) through the one-dimensional wave equation (Eq. (6)) as follows:

\[ \frac{\partial^2 u(z, t)}{\partial t^2} = \nu^2 \frac{\partial^2 u(z, t)}{\partial z^2} - \frac{3\beta B}{\rho} \frac{\partial T_l}{\partial z}, \quad (6) \]

where \( \rho \) is the mass density, \( \nu \) the sound velocity, \( \beta \) the linear thermal expansion coefficient, and \( B \) the bulk modulus. Using boundary conditions – continuities of both the stress at air/Co \( \left( 3\frac{1-\nu}{1+\nu} B \frac{\hat{u}}{\partial z} = 3\beta B \Delta T_l \right) \), Co/Al\(_2\)O\(_3\) \( \left( 3\frac{1-\nu}{1+\nu} B \frac{\hat{u}}{\partial z} - 3\beta B \Delta T_l = 3\frac{1-\nu}{1+\nu} B_{Al2O3} \frac{\hat{u}}{\partial z} \right) \) and the displacements at Co/Al\(_2\)O\(_3\) \( (u(z, t)\big|_{z=d, Co} = u(z, t)\big|_{z=d, Al2O3}) \) – \( u(z, t) \) were solved. Then, \( \eta_{qs}(t) \) was determined by matching \( u(0, t) \) with the Sagnac measurement curve, as shown in Fig. 1c. The parameter values used in the simulation are as follows: \( C_e = 6.6 \times 10^2 \text{ } T_e, C_l = 3.5 \times 10^6 \text{ } 46, \) and \( C_s = -W_{md}M^2/dT_s J/m^3 \cdot K^47 \), where a molecular field prefactor \( W_m \) was assumed to be \( 4.5 \times 10^8 \) for Co and \( 3.1 \times 10^6 \) for Al\(_2\)O\(_3\)\(^{48} \). \( \kappa_{Co} = 64 \) \(^{46} \) \( \kappa_{Al2O3} = 20 \text{ W/m} \cdot \text{K}^{49} \) at 500 K, \( B = 190 \text{ GPa}, \nu = 0.31 \) for Co\(^{46} \) and \( B = 240 \text{ GPa}, \nu = 0.28 \) for Al\(_2\)O\(_3\)\(^{50} \). For dynamic heat coupling coefficients between two sub-systems, we used following values:
$g_{el} = 1.3 \times 10^{18}$, $g_{ls} = 5.0 \times 10^{17}$, and $g_{es} = 3.5 \times 10^{17}$ W/m$^3$K to match with the $\Delta \theta_L(t)/\theta_L$ and $u(0, t)$ curves qualitatively. For the Curie-Weiss curve, $M(T) = M_s(1 - 1.058(T/T_c)^\alpha)^\zeta$ was extracted by fitting the data in ref. 51, here $M_s = 1360$ emu/cm$^3$, $T_c = 1380$ K, $\alpha = 3.15$, and $\zeta = 0.50$.

Author contributions

J.-W.K. conceived the experiment. J.-W.K. and Y.S. prepared TR-MOKE and Sagnac interferometer data. J.-R.J and C.V.P fabricated NiFe alloy films. J.-W.K. performed data analysis and simulation with the help of Y.S. J.-W.K. wrote the manuscript with the help of M.V and D.-H.K. All authors discussed the results and commented on the manuscript.

The authors declare no competing interests.
Figure captions

Fig. 1 Measurement geometry and ultrafast Sagnac interferometric data. a Simple images of the pump-probe MOKE and USI measurements. For MOKE, the front-pump and front-probe for the bilayer (left), the front-pump and back-probe schemes for the trilayer (middle) were used. The back-pump and front-probe for the bilayer (right) were used for the Sagnac measurements. b Dynamic strain profile $\eta(z, t)$ calculated for an infinite Co slab: the quasi-static strain $\eta_{qss}(z, t)$ and the propagating bipolar pulse $\eta_p(z, t)$. c Sagnac interferometric curves for Co bilayer: $\rho = \Delta R/R$ (red circles) and the lattice displacement $u(0, t)$ – experimental data (blue circles) and reproduced one by calculation (yellow line). d $\eta_{qss}(t)$ profile extracted from the reproduced data $u(0, t)$.

Fig. 2 Spin precession as a function of the pump intensity of the Co bilayer. a Differential magneto-optical Kerr rotations $\Delta \theta(t)$ of the Co(25) bilayer as a function of $I_p$ under $H_{ext} = 0.4$ T and $\phi = 60^\circ$. b Summary of the frequency change of the spin precession $\Delta f/f_m$ for the bilayer as a function of $I_p$ and $\phi$ (15°: black, 30°: red, 45°: green, 60°: blue circles). The pink circles present $\Delta f/f_m$ obtained from the Co(25) in the trilayer. c Model calculation results of $\Delta f/f_m$ based on the LLG equation in the presence (solid lines) and absence (dashed lines) of $\eta_{qss}$, respectively. d $\Delta \theta(t)$ induced by $\eta_p$ for the trilayer under $H_{ext} = 0.4$ T and $\phi = 60^\circ$.

Fig. 3 Ferromagnetic resonance frequency with the control parameters $T$, $\phi$, and $\eta_{qss}$. Contour maps of a ferromagnetic resonance frequency $f_r$ calculated using the classical Kittel equation as a function of $T$ and $\phi$ under $H_{ext} = 0.4$ T, for the absence (a for Co) and presence (b for Co and c for Ni) of $\eta_{qss}$, respectively. The $f_r$ decreases monotonically with increasing $T$ for case a but increases moderately, showing the inflection point around 800 K for case b, implying competition between the thermal and strain effects. The shaded boxes in b stand for the domains where $f_r$ increases (blue) and starts to slow down (red) as $T$ increases. d Selected curves of $\Delta f/f_m$ at $\phi = 25, 45$, and $60^\circ$ from Fig.
3c. \( \Delta \theta(t)/\theta \) of Ni(270)/SiO\(_2\) under \( H_{\text{ext}} = 0.4 \) T and \( \varphi = 25^\circ \) as a function of \( I_p \). Unlike the Co bilayer, the sign of \( \Delta f/f_m \) changes, as shown in the inset, confirming the competition between the thermal and QSS effects.

**Fig. 4 QSS effect governing spin dynamics.**

a) Calculated curves of spin dynamics based on the LLG equation for the absence (red) and presence (blue curve) of \( \eta_{\text{qss}} \) under \( H_{\text{ext}} = 0.54 \) T and \( \varphi = 60^\circ \). The \( \pi \)-phase inversion is clearly observed around 20 ps. The yellow dashed curve marks the monotonic-decaying background originated by a coherent rotation of \( H_{\text{eff}}(t) \) to the in-plane direction. Inset: schematic diagram describing the rotation direction of \( H_{\text{eff}}(t) \) depending on either QSS (blue) or thermal effect (red). b) Experimental verification of the \( \pi \)-phase inversion of the spin precession for materials with a negligible magnetoelastic energy (Ni\(_{0.36}\)Fe\(_{0.64}\) (red): \( \beta \sim 0 \), Ni\(_{0.8}\)Fe\(_{0.2}\) (blue circles): \( \lambda_s \sim 0 \)).
Figures

Fig. 1
Fig. 2
Fig. 3
Fig. 4

(a) \( -\Delta M_z/M_z \) vs. Time delay (ps) with and without \( \eta_{qss} \):
- Red line: without \( \eta_{qss} \)
- Blue line: with \( \eta_{qss} \)

(b) \( -\Delta \theta \) (norm.) vs. Time delay (ps) for different compositions:
- Red dots: \( \text{Ni}_{0.36}\text{Fe}_{0.64} \)
- Blue dots: \( \text{Ni}_{0.80}\text{Fe}_{0.20} \)

\( H_{eff} (t < 0) \) and \( H'_{eff} \):
- \( \lambda_s \eta_{qss} < 0 \)
- \( \lambda_s \eta_{qss} > 0 \)
