SUMMARY

Familial transthyretin amyloidosis (ATTR) is an autosomal-dominant protein-folding disorder caused by over 100 distinct mutations in the transthyretin (TTR) gene. In ATTR, protein secreted from the liver aggregates and forms fibrils in target organs, chiefly the heart and peripheral nervous system, highlighting the need for a model capable of recapitulating the multisystem complexity of this clinically variable disease. Here, we describe the directed differentiation of ATTR patient-specific iPSCs into hepatocytes that produce mutant TTR, and the cardiomyocytes and neurons normally targeted in the disease. We demonstrate that iPSC-derived neuronal and cardiac cells display oxidative stress and an increased level of cell death when exposed to mutant TTR produced by the patient-matched iPSC-derived hepatocytes, recapitulating essential aspects of the disease in vitro. Furthermore, small molecule stabilizers of TTR show efficacy in this model, validating this iPSC-based, patient-specific in vitro system as a platform for testing therapeutic strategies.

INTRODUCTION

Amyloidosis refers to a group of diseases caused by the extracellular deposition of misfolded fibrillar proteins, leading to multiorgan failure and death (Falk et al., 1997). Familial amyloidosis (AF) occurs when inherited point mutations in the genes coding for abundant serum proteins such as transthyretin (TTR), fibrinogen, lysozyme, or apolipoproteins lead to clinical disease. The most common form of AF arises from aggregation of mutated TTR, a 55 kDa transport protein predominantly synthesized by the liver (Connors et al., 2003; Falk et al., 1997; Planté-Bordeneuve and Said, 2011). Familial transthyretin amyloidosis (ATTR) is a lethal, autosomal-dominant disease caused by single amino acid substitutions arising from 1 of more than 100 described mutations in the TTR gene (Connors et al., 2003; online amyloidosis mutation database in Rowczenio and Wechalekar [2010]). These single amino acid substitutions destabilize the native homotrameric structure of circulating TTR, promoting release of amyloidogenic TTR monomers, fibril formation, and deposition as amyloid in target end organs (Ando et al., 2005; Falk et al., 1997). Most amyloidogenic TTR variants target the nervous system and heart, inducing neuropathy and cardiomyopathy (Jacobson et al., 1992, 1997; Planté-Bordeneuve and Said, 2011). The organ distribution and age of onset can vary across families and endemic areas, even with identical TTR mutations. Although transgenic mouse models and immortalized human cell lines have provided some insights into disease pathogenesis (Araki et al., 1994; Kohno et al., 1997; Reixach et al., 2004; Sousa et al., 2002; Tagoe et al., 2007), these systems are independent of the genetic context of the patient.

ATTR represents an important unmet medical need with significant morbidity and early mortality in affected families. Survival after ATTR disease onset is usually only 5–15 years (Benson et al., 2011; Planté-Bordeneuve and Said, 2011). Orthotopic liver transplantation is currently the only US-approved treatment for ATTR. However, only about one-third of patients are candidates for surgery (Monteiro et al., 2004), and cardiomyopathy and neuropathy may continue to worsen after transplantation. Recently, small molecule stabilizers of variant TTR (Tafamidis and dulfamisyl) shown to inhibit amyloid fibril formation in vitro are being studied in clinical trials (Berk et al., 2012; Coelho et al., 2012). Patient-specific, cell-based models are needed to facilitate the study of the genetic and epigenetic factors in this disease, permitting pharmacogenomic assessments of novel therapeutics.

The generation of induced pluripotent stem cells (iPSCs) through the reprogramming of somatic cells from patients with inherited diseases provides an unprecedented opportunity to study the effects of genetic abnormalities and disease progression. The derivation of unlimited quantities of...
the relevant cell types targeted and affected in patients with hereditary disease allows for the investigation of the cellular, molecular, and epigenetic events involved in a multisystem, genetic disease such as ATTR. Although most cases of ATTR are due to a single base pair mutation predominantly expressed in the liver, end organ damage occurs outside the liver, highlighting the need for a model capable of recapitulating the multisystem complexity of the disease.

Here, we describe the generation of ATTR patient-specific iPSCs and the directed differentiation of these cells into hepatic, neuronal, and cardiac lineages thereby modeling the three major tissue types involved in this disease (Figure 1). Our data are consistent with the clinical trial findings that known small molecule TTR stabilizers can inhibit TTR fibril formation in vivo, validating patient-specific iPSCs as a platform for testing therapeutics.

RESULTS

Generation of ATTR Disease-Specific Human iPSCs

Using our highly efficient and reproducible STEMCCA reprogramming system (Somers et al., 2010; Sommer et al., 2009, 2010), we generated iPSC lines from tissue samples of a patient heterozygous for the leucine-55-proline (L55P) TTR mutation (see Figure S1A available online). This mutation, one of the most clinically aggressive variants of ATTR disease (Jacobson et al., 1992), produces a highly unstable and amyloidogenic TTR, clinically target-

ing the heart and the peripheral nervous system (Lashuel et al., 1999). The sequenced TTR transcript from the reprogrammed ATTR-iPSC derivatives was compared to that from control iPSCs to confirm that the ATTR iPSCs carried the L55P mutation (Figure S1B). Characterization of each iPSC clone demonstrated normal 46 XX karyotype, expression of stem cell marker genes, and pluripotency in teratoma assays (Figures S1C–S1F). Characterized clones were then differentiated into both the effector cells (hepatocytes) that produce mutant TTR and peripheral target cells (neurons and cardiomyocytes) that are damaged by exposure to aberrant protein in order to create an iPSC-based, in vitro model of ATTR (Figure 1).

ATTR^{L55P} Disease-Specific Human iPSCs Can Be Directed into Hepatic-Lineage Cells that Secrete TTR

In ATTR, the deleterious effects of liver-produced TTR variants are seen in other organs, with the liver remaining phenotypically normal. The majority of patients with ATTR are heterozygous for one autosomal-dominant mutation in the TTR gene, although compound heterozygotes have been documented (Connors et al., 2003, 2009; Hammarström et al., 2001). Therefore, in most patients, TTR tetramers synthesized by the liver are comprised of a mix of normal and variant TTR monomers that assemble into stochastically formed homo- and heterotetramers (Schneider et al., 2001). To derive the full complement of TTR tetramer variants, containing posttranslational modifications that are normally present in patient serum TTR, we differentiated ATTR^{L55P} iPSCs into hepatic-lineage cells
with the aim of producing variant TTR protein from patient-derived cells.

In our system, the derivation of hepatic-lineage cells from iPSCs was achieved through a sequential, growth factor-driven differentiation process (Hay et al., 2008; Sullivan et al., 2010) (Figure 2A). Mimicking signaling events that occur during embryonic patterning, high levels of activin A and Wnt3a were used to drive iPSCs toward a definitive endoderm progenitor state. At this stage, the majority of the cells stained positively for CXCR4 and/or cKit (Figure 2B), cell surface markers for definitive endoderm (Yasunaga et al., 2005). Further maturation of the hepatic-lineage cells was achieved through culturing in maturation media containing hepatocyte growth factor (HGF) and oncostatin M (OnCM). As determined by quantitative PCR, the resultant hepatic-lineage cells express robust levels of hepatic markers apolipoprotein A1 (APOA1), albumin (ALB), alpha-fetoprotein (AFP), and, also importantly, TTR (Figure 2C).

Similarly, efficient derivation of hepatic-lineage cells and their precursor cell types was achieved from both ATTRL55P iPSCs and a control iPSC line as judged by comparable CXCR4 and cKit stainings at day 5 of differentiation (Figures 2B and S2A), TTR gene expression (Figure S2B), and functionally, the iPSC-derived, hepatic-lineage cells were capable of glycogen storage as determined by periodic acid Schiff (PAS) staining (Figures 2D and S2C). For the purposes of our in vitro disease model, we investigated whether the ATTRL55P iPSC-derived hepatic cells were capable of synthesizing and secreting TTR protein. Western blot analysis of serum-free conditioned media (hepatic supernatant [hs]) produced from ATTRL55P hepatic-lineage cells revealed the presence of TTR protein, indicating that iPSC-derived hepatic-lineage cells were indeed capable of TTR production and secretion, with the concentration of TTR in hs estimated to be in the range of 25–50 nM (Figure 2E). Moreover, mass spectrometric analysis was utilized to precisely characterize mutant and wild-type (WT) forms of TTR in hs, revealing the presence of TTRL55P in both control and ATTR L55P supernatants (Figure 2F). The ratio of ATTRL55P-to-TTRWT monomers in ATTR hs was calculated to be 1:2 rather than 1:1 as expected, suggesting that a proportion of the TTRL55P produced in hepatic-lineage cells is not secreted into the media, for reasons that are unknown.

Although it is the site of aberrant protein production in ATTR, the livers of patients with ATTR are thought to be relatively normal, escaping the cellular damage seen in other target tissues. However, there is some evidence to suggest that there could be physiological and molecular differences in ATTR livers. Examination of the liver in a transgenic murine model for a different form of amyloidosis, SSA (which involves the deposition of WT TTR), revealed a link between the levels of protein folding/chaperoning genes in the liver, and the degree of observable TTR deposition in the “target” cardiac tissue in aged transgenic mice. The livers of the young transgenic mice also exhibited increased expression of genes linked to protein trafficking and inflammation/immunity (Buxbaum et al., 2012).

Although control and ATTRL55P iPSC-derived hepatic cells express similar levels of hepatic markers, we were interested in the possible existence of gene expression signature differences between the two cell populations. To examine if this was the case, we performed microarray analysis to compare the transcriptomes of hepatic-stage cells derived from normal versus ATTRL55P iPSCs (three independent replicates per sample type). Hierarchical clustering analysis indicated segregation of the ATTRL55P iPSC-derived biological triplicates from the control samples (Figure S3A). KEGG and Biocarta analysis of the data set revealed that extracellular matrix and connective tissue genes including collagen, laminin, and integrin transcripts were overrepresented in control hepatic cells (Figures S3B and S3C). Interestingly, genes relating to protein folding and stress response, especially the heat shock protein 70 (hsp70) family genes, were among the main genes upregulated in ATTRL55P hepatic cells (Figures S3B–S3D), suggesting that the in vitro-derived, disease-specific hepatic cells upregulate these genes in response to the aberrant TTR protein.

**ATTRL55P iPSCs Can Be Directed into Target Cells of the Disease: Cardiomyocytes and Neurons**

The liver is not a clinically important site of amyloid deposition in vivo. Recapitulation of the ATTR disease phenotype requires a multilineage system to model complex interactions between the liver and target organ systems, including epigenetic events required for the full clinical phenotype to develop. The flexibility of the iPSC-based system allows for the directed differentiation of other tissue types, such as cardiomyocytes and neurons, that are affected by the variant protein produced by the liver. In initial studies, ATTRL55P iPSC-derived cardiac and neuronal cells were characterized with regards to gene expression profiling and functional assays.

The derivation of cardiomyocytes from ATTRL55P iPSCs was achieved using two methods. First, a modified growth factor-driven approach (Kattman et al., 2011; Yang et al., 2008) was used to efficiently obtain beating cardiomyocytes after 21 days of differentiation. A traditional embryoid body (EB) differentiation approach also successfully yielded beating cardiomyocyte colonies after only 10 days of differentiation (Figure 3A; Movie S1). A side-by-side comparison of the two methods through
Figure 2. Generation and Characterization of ATTL55P iPSC-Hepatic Lineage Cells

(B) Cells at day 5 of differentiation express the definitive endoderm cell surface markers CXCR4 and cKit, as determined by FACS analysis.

(legend continued on next page)
quantitative PCR analysis indicated that the EB approach was more efficient at yielding cardiomyocyte cells (as judged by the end-stage cardiomyocyte marker cTNT) (Figure 3B; data not shown). In addition to this, a high proportion of cells in cardiac EB (cEB) cultures express the cardiac marker sarcomeric anti-actinin as determined by intracellular FACS analysis (Figure 3C), and this method was therefore used to generate cardiomyocytes for subsequent experiments.

For the derivation of neuronal-lineage cells, a modified stepwise-directed differentiation approach was used to obtain neuronal-lineage cells from iPSCs based on a previously described protocol by Chambers et al. (2009) and Hu et al. (2009). Morphologically, the cells produced resemble neuronal cells with long dendritic processes and axon-like structures (Figure 4A). Immunofluorescence characterization revealed that early-stage cells were positive for neuronal class III β-tubulin (TUJ1) (Figure 4B), whereas late-stage differentiation cells expressed microtubule-associated protein 2 (MAP2) and choline acetyltransferase (ChAT), proteins that localize to the cytoplasm of neuronal cells and the latter an enzyme that is critical for the production of the neurotransmitter acetylcholine (Figure 4C). Real-time PCR analysis demonstrated the expression of transcripts for TUJ1 and homeobox protein 9 (HB9), a motor neuron-specific marker (Figure 4D).

Studies have suggested that target cells affected by amyloidogenic TTR internalize and modify the variant protein in a process that may contribute to fibrillogenesis (Fleming et al., 2007, 2009). We examined whether ATTRL55P iPSC neuronal-lineage cells were capable of taking up fluorescently labeled WT or L55P recombinant human TTR protein. As demonstrated in Figure 4E, cells incubated with either labeled WT or L55P TTR contained foci of fluorescence in the cytoplasm, demonstrating that the cells were indeed capable of TTR internalization, similar to their in vivo counterparts. Interestingly, iPSC-derived cardiac cells did not demonstrate this property (data not shown).

Patient-Specific Recapitulation of Target Tissue Damage In Vitro
Having successfully derived the tissue types involved in ATTRL55P from patient-specific iPSCs, we then assessed the cellular and molecular effects of exposure to aberrant...
TTR in the directly differentiated target cells. To do this, serum-free conditioned media (hs) were harvested from control and ATTRL55P iPSC-derived hepatic cells for use in subsequent TTR exposure experiments in the neuronal- and cardiac-lineage target cells.

ATTRL55P iPSC-derived neuronal and cardiac-lineage cells were cultured with media containing either control or ATTRL55P hs, which was added to normal culture media in a 1:1 ratio. After an extended period of exposure (≥12 days), there was no noticeable difference in the morphology of the neuronal cells, and no visible protofilaments or aggregates were present in the cultures (Figure 5A). Similar observations were made for the cardiac cells after 6–10 days of exposure (Figure 5B). These results were in contrast to those seen when iPSC-derived neuronal cells and a neuroblastoma cell line (SY5Y) were exposed to human recombinant L55P TTR protein; clear aggregate formation was noted in these cultures, but not in cultures dosed with WT TTR protein (Figures S4A and S4B). The L55P protein aggregates stained positively for the ATTR amyloid binding chemical, thioflavin T (Figure S4C).

Although there was no observable difference in the morphology of cells exposed to either control or ATTRL55P hs, a number of genes previously reported to be associated with ATTR disease progression were upregulated in both iPSC-derived neuronal and cardiac cells exposed to ATTRL55P hs. In particular, the stress-response markers, macrophage colony stimulating factor (M-CSF) and heme oxygenase 1 (HO1), were upregulated (Figures 5C and 5D; asterisks denote statistically significant differences as compared to control samples, as determined by Student’s t test analysis). These genes were previously reported to be associated with ATTR in murine model systems and in neuronal biopsy samples of patients with ATTR (Sousa et al., 2001a, 2001b, 2005). The expression of protein folding genes was also examined in control and ATTRL55P hs-exposed cells based on the observation that higher levels of these genes were seen in ATTRL55P iPSC-derived hepatic-lineage cells (compared to disease-free controls) by microarray analysis (Figure S3). Of the interrogated genes, the hsp70 gene, hspA1A, was upregulated in neuronal-lineage cells exposed to ATTRL55P hs, but not to a significant level (Figures 5C and 5D).

In addition to these marked gene expression changes, Hoechst 33342 and propidium iodide (H-PI) staining revealed that both neuronal and cardiac cells exposed to ATTRL55P hs displayed statistically significant decreased cell survival, although no overt morphological changes were noted. Cell survival was ascertained by a decrease in

Figure 4. Derivation of Neuronal-Lineage Cells from ATTRL55P iPSCs that Are Capable of TTR Internalization
(A) Phase-contrast image shows neuronal cells derived from ATTRL55P iPSCs.
(B) Immunofluorescence staining presents ATTRL55P iPSC-derived neuronal cells for the neuronal marker TUJ1 (red). Nuclei were stained with DAPI (blue).
(C) Immunofluorescence staining shows ATTRL55P iPSC-derived neuronal cells for the MAP2 (red). Nuclei were stained with DAPI (blue).
(D) Quantitative PCR analysis of derived neuronal-lineage cells compared to undifferentiated iPSCs and human brain cDNA is shown. Neuronal cells exhibit upregulated levels of TUJ1 and motor neuron homebox transcription factor HB9. All independent biological samples (n = 3) were normalized to GAPDH. Error bars, SD.
(E) ATTRL55P iPSC neuronal-lineage cells are capable of TTR (both WT and L55P) internalization as demonstrated by exposure to AF488-labeled human recombinant proteins. Foci of labeled proteins (green fluorescence) are visible in the cells. Nuclei were stained with DAPI (blue).
the proportion of cells in the FSC versus SSC gate and an increase in PI-positive cells (representative flow cytometry results in Figures 5E and 5F with compiled results in Figures 6B and 6D). Similar results had previously been observed in preliminary experiments ascertaining the effect of recombinant human WT or L55P TTR on cell survival in iPSC-derived neuronal (Figure S4A) and cardiac (Figure S4B) cultures.

Thus, iPSC-derived hs containing amyloidogenic L55P TTR had a deleterious effect on cell survival compared to the proportion of cells in the FSC versus SSC gate and an increase in PI-positive cells (representative flow cytometry results in Figures 5E and 5F with compiled results in Figures 6B and 6D). Similar results had previously been observed in preliminary experiments ascertaining the effect of recombinant human WT or L55P TTR on cell survival in iPSC-derived neuronal (Figure S4A) and cardiac (Figure S4B) cultures.

Thus, iPSC-derived hs containing amyloidogenic L55P TTR had a deleterious effect on cell survival compared to recombinant human WT or L55P TTR on cell survival in iPSC-derived neuronal (Figure S4A) and cardiac (Figure S4B) cultures.

Figure 5. iPSC-Based Modeling of ATTR In Vitro; ATTR^{L55P} hs Deleteriously Affects iPSC-Derived Target Cells
(A) Mature ATTR^{L55P} iPS cells were exposed to hs from either control iPS or ATTR^{L55P} iPS hepatic-lineage cells. No discernable differences in cell morphology and no visible protein aggregation were seen after 10 days. Images, 20x magnification.

(B) Cardiomyocytes derived from ATTR^{L55P} iPSs were exposed to hs for 6 days. There were no visible differences in the cultures containing control hs and ATTR^{L55P} hs (20x magnification).

(C and D) Gene expression analysis of day 12-dosed ATTR^{L55P} neuronal cells (C) and day 10-dosed ATTR^{L55P} cardiac cells (D) for a panel of markers associated with stress response and protein folding. Error bars, SD. Asterisks (*, **) denote t test significance at the 5% and 1% level, respectively. Sample size is n = 2 from independent experiments. ATTR^{L55P} samples were normalized to controls for each experiment.

(E) ATTR neuronal cells cultured in media containing hs for 19 days were analyzed for the uptake of PI and Hoechst 33342. Cultures dosed with ATTR^{L55P} hs contained fewer live cells (forward versus side scatter gate; Hoechst-positive gate, annotated) compared to control hs cultures.

(F) ATTR^{L55P} cardiac cells dosed for 10 days with media containing ATTR^{L55P} hs exhibited a decrease in cell viability compared to control cultures.
Figure 6. The Deleterious Effects of ATTR<sup>L55P</sup> hs Can Be Abrogated by Small Molecule TTR-Stabilizing Agents

(A) ATTR<sup>L55P</sup> iPSC-derived neuronal-lineage cells were exposed to control and ATTR<sup>L55P</sup> hs in the presence or absence of diflunisal (20 μM) and flufenamic acid (10 μM). Cells were harvested and examined for their H-PI positivity by flow cytometry. Increased apoptosis and cell death seen in ATTR<sup>L55P</sup> hs cultures were rescued in cultures also containing the small molecule compounds.

(B) Neuronal live-cell proportions in cultures dosed with ATTR<sup>L55P</sup> hs for 12 days, ± compounds, compared to control hs-dosed cells. Error bars, SD. Asterisks (*) denote t-test significance at the 5% and 1% level, respectively. p Values are denoted in the graph. Sample sizes (from independent experiments) are ATTR<sup>L55P</sup> n = 4, ATTR<sup>L55P</sup> + Diflu n = 3, and ATTR<sup>L55P</sup> + Fluf n = 3. n.s., not significant.

(C) ATTR<sup>L55P</sup> iPSC-derived cardiac cells were dosed for 6 days and analyzed for Hoechst-PI positivity in the same manner.

(D) Cardiac live-cell proportions in cultures dosed with ATTR<sup>L55P</sup> hs, ± compounds, compared to control hs-dosed cells. Error bars, SD. Asterisks (*) denote t-test significance at the 5% and 1% level, respectively. p Values are denoted in the graph. Sample sizes (from independent experiments) are ATTR<sup>L55P</sup> n = 3, ATTR<sup>L55P</sup> + Diflu n = 3, and ATTR<sup>L55P</sup> + Fluf n = 3.
supernatant from control-iPSC hepatocytes. Through the examination of previously identified ATTR-associated genes and genes identified through our iPSC-derived hepatic-lineage microarray screen, we were able to determine that ATTRL55P hs exposure upregulated several ATTR disease-associated genes in target cells, in a manner that is similar to some reported observations in both in vivo and in vitro systems.

Small Molecules Can Ameliorate the Damaging Effects of ATTRL55P Exposure in an iPSC-Based, Multisystem Model of ATTR

In vitro and clinical data demonstrate that small molecules complexing with TTR at the thyroxine binding site can stabilize the native tetramer, preventing amyloid fibril formation, and inhibiting disease progression (Coelho et al., 2012; Miller et al., 2004; Peterson et al., 1998; Sekijima et al., 2006; Tojo et al., 2006). To determine the effect of TTR stabilizers in our iPSC-derived multiorgan model of ATTR, we examined the effect of identified TTR-responsive small molecules on ATTRL55P hs-induced apoptosis of iPSC-derived cardiac and neuronal-lineage cells.

To ascertain whether diflunisal and flufenamic acid, two thyroxine-mimetic small molecule TTR stabilizers, negate the deleterious effects of ATTRL55P hs, these compounds were added to ATTRL55P hs for dosing experiments with neuronal and cardiac cells at final concentrations of 20 and 10 μM, respectively. As demonstrated in Figure 6, the addition of the small molecules to ATTRL55P hs had a protective effect on both neuronal and cardiac cell survival compared to cells exposed to ATTRL55P hs alone, as judged by H-PI stainings of dosed cells. Although exposure of both neuronal and cardiac cells to ATTRL55P hs led to a statistically significant decrease in cell survival compared to control hs samples (Figures 6B and 6D), addition of small molecule compounds resulted in increased cell survival (close to, but not significantly different compared to ATTRL55P hs for ATTRL55P +diflunisal; significant for ATTRL55P +flufenamic acid). These drugs were also capable of preventing recombinant human L55P TTR protein from forming microscopically visible protofilaments in cultures of patient iPSC-derived neuronal cells and SYSY neuroblastoma cells, as assessed by thioflavin T binding (Figures S4C–S4E). These experiments demonstrate that an iPSC-based, multisystem, in vitro model can serve as a valuable platform for the testing of novel therapeutics in the genetic context of the patient.

DISCUSSION

Human iPSC-based disease modeling provides an opportunity to recapitulate a disease phenotype in the context of a patient’s exact genetic background. In the case of ATTR, patients with the same genetic mutations have been shown to exhibit variable patterns of disease progression (Planté-Bordeneuve and Said, 2011), highlighting the involvement of genetic modifiers of disease.

ATTR is an unusual hereditary disease that manifests clinically in adulthood with no reproductive pressure against transmission of the disease. Until recently, diagnostics were not available, and carriers could not be identified before clinical disease onset, which typically occurs in the fourth decade or later. In patients affected with the TTRLL55P mutation, the age of disease onset is earlier and the clinical outcome more severe (Jacobson et al., 1992), characteristics that reflect greater instability of the mutant TTR tetramer (Lashuel et al., 1998, 1999). Our work documents the successful modeling of ATTR in vitro with the use of iPSC technology, demonstrating that it is possible to model a long-term, complex, multisystem disease in a relatively short space of time, using lineage-specified cells derived from patient-specific stem cells.

iPSCs have been utilized to model genetic diseases in a single lineage in which the variant protein functions, for example, Fanconi anemia (Raya et al., 2009), alpha 1 antitrypsin deficiency (Rashid et al., 2010), and amyotrophic lateral sclerosis (Dimos et al., 2008). Our work demonstrates that iPSC technology can be used to model a multisystem disease in which the effects of variant protein produced by one organ manifests disease in other target tissues.

The mechanism by which variant TTR adversely affects cells is still being elucidated. It is postulated that abundant extracellular amyloid fibril deposits seen in patient biopsies have a disruptive effect on tissue architecture and organ function, but recent evidence suggests that TTR monomers and/or oligomeric prefibrillar protein structures are toxic to cells (Reixach et al., 2004; Sousa et al., 2001a, 2002). We have recapitulated a part of this process in a patient-specific fashion in vitro. In our iPSC-based disease model, the lack of visible protofilament/aggregate material in ATTRL55P hs cultures suggests that the negative effect of ATTRL55P hs is likely to be due to monomer or oligomer-induced cytotoxicity, reported by others to be a mechanism of cellular damage (Reixach et al., 2004; Sousa et al., 2002).

Although extended exposure to ATTRL55P hs increased apoptosis in both neuronal and cardiac cells, we were interested in examining some of the molecular changes in the exposed target-lineage cells. Based on the previously discussed microarray data obtained through the comparison of hepatic cells derived from normal or ATTRL55P-specific iPSCs (Figure S2), we focused on expression of hsp70 family genes that are involved in protein folding and upregulated in response to cellular stressors. These genes have been studied in a range of protein-misfolding disorders,
including Alzheimer’s disease (Hoshino et al., 2011). Intriguingly, an ATTR mouse model with impaired heat shock response exhibits a comparatively accelerated amyloid deposition pattern, implicating the importance of these genes for the regulation of the process of ATTR amyloidogenesis (Santos et al., 2010). We also examined the expression of markers previously reported to be associated with ATTR in other model systems and patient tissues, such as M-CSE, p21, and antioxidant enzyme HO1 (Sousa et al., 2001a, 2001b, 2005), and the receptor for advanced glycation end products (RAGE), a marker that has been postulated as a mechanism through which variant TTR targets certain tissues for amyloid deposition and cytotoxic effects (Sousa et al., 2001b). Through the examination of these markers in the exposed target-lineage cells, we were able to determine a pattern of gene expression upregulation in ATTRL55P hs-exposed cells that was accordant with previous observations. This iPSC-based, in vitro system may therefore prove to be a valuable model system in which to further dissect the molecular mechanisms through which aberrant TTR affects ATTR disease target cells and tissues. Moreover, it is interesting that in our system, iPSC-derived ATTRL55P hepatic cells exhibit gene expression differences compared to control cells because the livers of patients with ATTR are thought to be comparatively normal despite being the site of aberrant TTR production. Recent findings from a murine SSA model also suggest that the liver has a role to play in the degree of amyloidogenesis in target tissues, through a novel long-range chaperoning effect (Buxbaum et al., 2012). The iPSC-based system may prove to be an ideal platform in which to further investigate the role of the liver in ATTR amyloidogenesis.

The ability of diflunisal and flufenamic acid, known TTR tetramer stabilizers, to prevent iPSC-derived target cell death in the presence of ATTRL55P hs validates this system as a potential platform in which to test novel therapeutic agents. Different approaches to therapeutically target the cause and symptoms of ATTR have been tested in vitro and in vivo systems, with several progressing onto human clinical trials. Examples include the reduction of serum level TTR through the use of antisense technology (Ackermann et al., 2012), and the design of small molecule compounds with the aim of either kinetically stabilizing aberrant TTR heterotetramers (Alhamadsheh et al., 2011; Connelly et al., 2010) (thus slowing the rate-limiting step in the process of amyloidogenesis) or disruption of existing amyloid fibrils and prefibrillar aggregates (Cardoso et al., 2010; Ferreira et al., 2012). Patients with ATTR form amyloidogenic protein based on 1 of over 100 point mutations in the TTR gene (Connors et al., 2003). The binding affinity of small molecule inhibitors to different variant TTRs varies significantly, predicting mutation-unique responses to specific TTR stabilizers (Tojo et al., 2006), an indicator that a one-size-fits-all approach to ATTR treatment may not be feasible. Generation of differentiated, iPSC-derived, ATTR disease-specific cells permits variant TTR-specific screening of potential therapeutic molecules, overcoming issues of incomplete mutation representation in clinical trials of this rare orphan disease. These cells also provide a model system in which to study genetic modifiers of TTR secretion, and cytoprotective agents that inhibit toxic signaling pathways in the target cells. Based on the fact that these disease-specific cells are pluripotent and can be stored and expanded indefinitely, they will serve as a permanent repository for researchers around the world as a valuable tool for investigating potential new targets for drugs modulating protein misfolding and aggregation.

**EXPERIMENTAL PROCEDURES**

**STEMCCA Lentivirus Production, iPSC Generation and Maintenance, and Teratoma Formation Assay**

hSTEMCCA virus production and concentration (Sommer et al., 2009, 2010) and iPSC generation, maintenance, and validation were carried out as previously described by Somers et al. (2010). For this study, fibroblasts from a 27-year-old female patient heterozygous for the L55P TTR mutation were used to create three clonal disease-specific lines. The three control iPSC lines used in this study were obtained from the Boston University and Boston Medical Center’s Center for Regenerative Medicine (CReM) comprehensive iPSC bank (http://www.bumc.bu.edu/stemcells/crem-ips-cell-bank/) and were matched with the disease-specific lines for age, gender, and ethnicity.

**Generation of Hepatic-Lineage Cells from iPSCs**

Differentiation of iPSCs toward the hepatic lineage was carried out as described by Hay et al. (2008) and Sullivan et al. (2010). For the collection of media supernatants from hepatic-lineage cells, the end-stage differentiated cells were washed with PBS and incubated in serum-free media (L-15 [Leibovitz] medium, 10% KnockOut Serum Replacement [KSR], and Penicillin-Streptomycin-Glutamine, which were all from Invitrogen). The media were harvested and replaced every 24 hr up to 3 days. See the Supplemental Experimental Procedures for details regarding microarray analysis of iPSC-derived hepatic-lineage cells. For the FACS analysis of definitive endoderm markers, trypsin-dissociated cells were stained with human CXCR4-biotin/strepavidin-FITC and cKit-PE (eBiosciences) antibodies and analyzed on an LSRII (BD Biosciences) using FACsDivaperm...
(HyClone), 1% NEAA (Invitrogen), 100 mM 2-mercaptetanethanol for 7 days. The resultant EBs were transferred to gelatin-coated tissue culture plates. Media were changed every 3 days.

For intracellular staining of cEB cells for sarcomeric anti-actinin, trypsin-dissociated 4% parafomaldehyde (PFA):PBS-fixed cells were washed and stained in PBS/5% FBS/0.5% saponin. The primary antibody was sarcomeric anti-actinin (Sigma-Aldrich), the isotype control was mouse IgG1 κ, and the secondary antibody was FITC anti-mouse IgG (both from BD PharMingen). Analysis was carried out on an LSR II flow cytometer.

**Generation of Neuronal-Lineage Cells from ATTR<sup>155P</sup> iPSCs**

Neuronal-lineage cells were generated as previously described by Chambers et al. (2009) and Hu et al. (2009). For immunofluorescence visualization of TUJ1, MAP2, and ChAT, cells were grown on 18 mm glass coverslips coated with 5 μg/ml fibronectin and 10 μg/ml laminin (for TUJ1, MAP2 stainings) or Matrigel (for ChAT stainings). Cells were fixed with 4% PFA in PBS and permeabilized and blocked with 5% BSA in PBS with 0.1% Triton X-100. Primary and secondary antibody stainings were carried out in PBS/0.005% Triton X-100. Primary antibodies were mouse anti-human TuJ1, mouse anti-human MAP2 (Sigma-Aldrich), and rabbit anti-human ChAT (Millipore). Secondary antibodies were donkey anti-mouse 594 nm and donkey anti-rabbit 488 nm (Jackson ImmunoResearch). Cell nuclei were stained with DAPI (Molecular Probes) after antibody incubations and final washes.

**PAS Assays**

PAS assays were carried out on adherent cell cultures in 6-well plates, based on manufacturer recommendations (Invitrogen). Cells were visualized and photographed using a Nikon Eclipse TS100 microscope and SPOT software (SPOT Imaging Solutions).

**Immunoblot Analysis**

A total of 25 ng of purified human serum TTR (Sigma-Aldrich), hepatic-iPSC supernatant, and KSR-based media control samples were analyzed by SDS/PAGE using a 12% homogeneous gel under reducing conditions. Rabbit anti-human TTR (DAKO) and HRP-conjugated goat anti-rabbit IgG (Santa Cruz Biotechnology) were used for TTR detection. The immunoblot was developed using the ECL Plus Western Blotting Detection Reagent (GE Healthcare).

**Mass Spectrometry**

TTR protein was purified from culture supernatants by immunoprecipitation and characterized by electrospray ionization (ESI) mass spectrophotometry (Lim et al., 2002).

**Thioflavin T Assay**

Cell and media cytospins were fixed in 4% PFA for 10 min, washed with distilled water, and stained with 1% thioflavin T solution for 5 min. The cells were then differentiated in 70% ethanol and rinsed twice with distilled water before being mounted for microscopy under polarized light.

**RNA Extraction, and Semiquantitative and Quantitative PCR**

The RNeasy Micro Kit (Qiagen), DNA-free Kit (Ambion), and High Capacity CDNA Reverse Transcription Kit (Applied Biosciences) were used for the extraction and purification of RNA and cDNA synthesis, all according to manufacturer instructions. Quantitative PCR was conducted using SYBR Green Real-Time PCR Master Mix (Applied Biosystems) and StepOne Real-Time PCR machines (Applied Biosystems). See Table S1 for a list of primers. Where appropriate, Student’s t test statistical analyses were carried out to determine if there were significant differences between sample groups.

**Cell Viability Assays**

For dosing experiments involving hs, filtered supernatants collected from iPSC-hepatic cultures were diluted 1:1 with neuronal/cardiac growth media as appropriate before addition to cell cultures. For experiments involving small molecules, diflunisal and flufenamic acid were added to supernatants and incubated at 4°C overnight before addition to cell cultures (final concentrations, 20 and 10 μM, respectively). Dosed cell cultures were trypsin dissociated and washed with PBS-5% FBS before incubation with 8.8 ng/ml Hoechst 33342 (Sigma-Aldrich) at 37°C for 15 min. After washes, the cells were incubated with PI (Invitrogen) and immediately analyzed by flow cytometry (LSRII). For statistical analyses, a value for cell survival for each sample was calculated from the proportion of cells in the FSc versus SSc gate and the proportion of Hoechst-positive, PI-negative cells within this population. Samples were normalized to the control sample for each experiment. Student’s t tests were conducted to compare ATTRL55P to control, ATTRL55P plus diflunisal, and ATTRL55P plus flufenamic acid groups. See the Supplemental Experimental Procedures for details of experiments involving recombinant TTR protein.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Supplemental Experimental Procedures, four figures, one table, and one movie and can be found with this article online at http://dx.doi.org/10.1016/j.stemcr.2013.10.003.

**ACKNOWLEDGMENTS**

Funding was provided by the Amyloid Foundation (to G.J.M. and A.L.), grant NIH R01AG031804 (to L.H.C. and C.M.K.), grants R01 NS051306 and FDA FD-R-002532 (to J.L.B.), the Young Family Amyloid Research Fund (to L.H.C., C.M.K., and J.L.B.), and the Boston University Clinical and Translational Science Institute (CTSI) (to G.J.M.).
