Abstract. To investigate the effects of different cryoprotectants on germination and seedling development of jatropha (Jatropha curcas L.) seeds after cryopreservation, two experiments were performed under in vitro and ex vitro conditions. Nine treatments were used for both experiments, as follows: T1—No cryoprotectants (control); T2—glycerol 2 M (20 minutes); T3—sucrose 0.4 M (20 minutes); T4—glycerol 2 M (20 minutes) + PVS2 (10 minutes); T5—glycerol 2 M (20 minutes) + PVS2 + phosphogluconol 1% (10 minutes); T6—sucrose 0.4 M (20 minutes) + PVS2 (10 minutes); T7—sucrose 0.4 M (20 minutes) + PVS2 + phosphogluconol 1% (10 minutes); T8—glycerol 2 M (20 minutes) + sucrose 0.4 M (20 minutes) + PVS2 (10 minutes) and T9—glycerol 2 M (20 minutes) + sucrose 0.4 M (20 minutes) + PVS2 (10 minutes) + phosphogluconol 1% (10 minutes). After cryopreservation, seeds without cryoprotectants (T1) or with sucrose 0.4 M + PVS2 (T6) returned the best germination percentages after seven days of in vitro culture, 29.5% and 25%, respectively. However, they were not significantly different. For the ex vitro experiment, seed germination percentage was higher in organic substrate. These results indicate that cryopreservation of jatropha seeds can be accomplished without cryoprotectants, and faster germination is obtained in organic substrate.

Jatropha (Jatropha curcas L.) has been considered a promising species for biofuel production. However, jatropha is still considered undomesticated and breeding and genetic improvement programs are needed. In this context, germplasm collection and evaluation are essential for breeding new cultivars with high yield, good quality, and wide adaptation (Cai et al., 2010).

Conservation of seed-propagated plants is relatively easy for seeds with orthodox type of storage behavior, such as jatropha. In this case, the viability can be maintained by drying the seeds and storing at low temperatures. The ex situ preservation of orthodox seeds in gene bank has been the most effective strategy for plant genetic resources conservation. Today, about six million accessions are conserved worldwide in more than 1000 gene banks as ex-situ germplasm collections (Rahaman and Sivaraj, 2013). It is therefore important that investors, planning commercial production of biodiesel with jatropha seeds as feedstock, do not have to store the seeds for long time, especially under open air conditions as the oil yield and free fatty acid content are affected by storage time and improper storage condition (Akowuah et al., 2012).

Prada et al. (2015) emphasized the use of biotechnological techniques, such as micropropagation and cryopreservation, as relevant tools to improve the possibilities for multiplication of genotypes of interest and long-term conservation of germplasm. Cryopreservation of seeds allows the long-term preservation of biological material at ultra-low temperatures (~196 °C) in liquid nitrogen (LN) or in its vapor phase (between ~154 °C and ~196 °C) (Araújo et al., 2016). This procedure reduces the metabolism drastically and allows the plant material to reach a state whereby cellular division is halted, keeping its feasibility for a long period (Kaviani, 2011; Reed, 2008).

The main event that limits the survival of cryopreserved tissues using conventional freezing techniques is the possible ice formation within the extracellular matrix of multicellular tissues (Taylor et al., 2015). Therefore, new protocols have been developed involving the use of cryoprotectants to allow cooling of plant cell contents into a vitrification state without the formation of ice crystals (Engelmann, 2011; Nadarajan and Pritchard, 2014; Taylor et al., 2015). The plant vitrification method involves the use of an extremely concentrated solution (7–8 M) of cryoprotectants [plant vitrification solution (PVS)] to allow plant tissues to reach a vitrification state and prevent ice crystal formation (Niino and Arizaga, 2015).

The most applied vitrification solution is the PVS2, which contains 30% (w/v) glycerol, 15% (w/v) ethylene glycol, 15% (w/v) dimethyl sulfoxide, and 0.4 M sucrose in basal Murashige and Skoog (MS) medium (Matsumoto and Niino, 2014).

Cryoprotectants are important for cell survival, but they can also cause some complex stresses, such as osmotic injury and dehydration stress (Uchendu et al., 2010). Sugars, such as sucrose, trehalose, and glucose, have been used as cryoprotectants and are regarded as vitrification agents without causing toxicity to plant cells (Benson and Brenner, 2004). A more recently used cryoprotectant is phloroglucinol (1,3,5-trihydroxybenzene) or phloroglucin (PG tautomer), a benzenetriol that has growth regulating properties (Perez et al., 2016; Teixeira da Silva et al., 2013) and improves recovery of cryopreserved protocorms (Vendrame and Faria, 2011).

In jatropha, in vitro seed cryopreservation protocols have been developed, but some problems related to this procedure have been reported, such as decrease in seed germination percentage (Salomão et al., 2016), low development of explants in vitro from cryopreserved seeds (Prada et al., 2015), and seedlings with reduced vigor and significant increase in abnormal plants (Silva et al., 2012). Therefore, the development of new cryopreservation protocols using alternative cryoprotectant combinations could improve the efficiency of this technique. The present study was performed to investigate the effects of different cryoprotectants on germination and seedling development of J. curcas in vitro and ex vitro.

Material and Methods

Location, plant material, and seed sterilization

A total of 12 hybrid plants were selected from a jatropha field plot at the University of Florida’s Tropical Research and Educational Center (TREC) (25°50’ N and 80°50’ W, 3.8 m above sea level), in Homestead, FL. The 4-year-old hybrid plants were obtained from intraspecific crosses between jatropha accessions from COSTA Rica and Mexico. The cryopreservation experiments for this study were performed in the Ornamental Horticulture’s laboratory and greenhouse, both at TREC (Fig. 1).
J. curcas seeds obtained after crosspollination were collected from twelve 4-year-old hybrids and stored in paper bags under laboratory conditions for three days. The mean values for length, width, 100 seed weight, and water content of these 4-d-old seeds before the cryopreservation process in LN were 1.70 cm, 1.87 cm, 71.38 g, and 6.9%, respectively, which is suitable for this species (Salomão et al., 2016). Seeds were washed in distilled water, followed by surface sterilization with 1% Alconox (Alconox, New York, NY) solution, and then successive distilled water rinses. Then, seeds were transferred to a laminar flow hood and were sterilized with 3% sodium hypochlorite for 5 min, followed by three 3-min rinses in sterilized distilled water.

Seed cryopreservation

After sterilization, seeds were dried on autoclaved tissue paper for 5 min and placed in LN for 96 h. For each treatment, six Falcon 15-mL conical centrifuge tubes (11.8 cm length × 1.7 mm o.d.) containing five seeds each were used. Different cryoprotectants were evaluated either alone or in 1:1 combination (v:v). Nine treatments were evaluated for both in vitro and ex vitro experiments, as follows:

- **T1**—No cryoprotectants (control);
- **T2**—Glycerol 2 M (20 min);
- **T3**—Sucrose 0.4 M (20 min);
- **T4**—Glycerol 2 M (20 min) + PVS2 (10 min);
- **T5**—Glycerol 2 M (20 min) + PVS2 + Phloroglucinol 1% (10 min);
- **T6**—Sucrose 0.4 M (20 min) + PVS2 (10 min);
- **T7**—Sucrose 0.4 M (20 min) + PVS2 + Phloroglucinol 1% (10 min);
- **T8**—Glycerol 2 M (20 min) + Sucrose 0.4 M (20 min) + PVS2 (10 min);
- **T9**—Glycerol 2 M (20 min) + Sucrose 0.4 M (20 min) + PVS2 (10 min) + Phloroglucinol 1% (10 min).

After 96 h in LN, Falcon tubes were removed and seeds rapidly thawed in a water bath at 40 °C for 2–3 min, and the cryoprotectant solutions removed from the tubes. Seeds were then washed in distilled water, dried on paper tissue for 5 min, and experiments 1 and 2 carried out.

**Experiment I: In vitro germination and seedling growth from cryopreserved seeds.** After cryopreservation, the seed testa was removed (Danso et al., 2011), and the remaining cotyledon and embryo were placed in magenta G-7 vessels (Magenta Corp., Chicago, IL) containing MS basal culture medium (Murashige and Skoog, 1962) solidified with 7 g l−1 agar (Fisher®, Chicago, IL) for germination. The medium pH was adjusted to 5.7 before autoclaving at 121 °C for 15 min at 1.2 kg·cm−2. In vitro seed cultures were maintained under controlled environmental conditions; 27 ± 2 °C; 52 µmol·m−2·s−1; 16/8 light/dark using Philips® LED top lighting (Fig. 1A).

Germination (G), oxidation (O), and contamination (C) percentages, as well as shoot length (SL) and root length (RL), and the number of roots (NR) of seedlings were evaluated at 7 d after sown (DAS). In addition, shoot fresh weight (SFW) and root fresh weight (RFW), as well as shoot dry weight (SDW) and root dry weight (RDW) per seedling were determined at the final evaluation of this experiment (14 DAS). SDW and RDW were determined after oven drying at 80 °C for 2 d.

**Experiment II: Ex vitro germination and seedling growth from cryopreserved seeds.** This experiment was performed in the greenhouse assessing the same treatments used for the in vitro experiment. Seeds were sown in 1-L-L plastic black pots containing a commercial garden soil used as substrate (Miracle-Gro® Garden Soil All Purpose, NP K 0.09%–0.05%–0.07%). Germination was recorded every day from the date of sowing and continued till the germination ceased (Fig. 1B).

We used six replicates of five seeds each to calculate 1) the initial percentage of seeds that germinated [G% = (ni/N) × 100]; 2) the final germination percentage [Gf% = (nf/N) × 100], where ni and nf were, respectively, the number of seeds germinated at first evaluation (4 DAS) or at the end of the whole experiment (10 DAS), and N was the number of seeds included in the test; 3) the germination speed index [GSI = ∑[ni/ti]], where ti was time (day i) and; 4) the average germination time [AGT = ∑[ti·ni]/∑ni], where N is the final number of seeds that germinated and ni was the cumulative number of seeds germinated by adjacent counts at times ti (Sneideris et al., 2015). Germination was defined as the visible emergence of the seedling hypocotyl.

In the final assessment of this study (10 DAS), seedlings were uprooted carefully to estimate the SL, SFW, RFW, SDW, and RDW per seedling.

**Statistical design and data analysis**

Six replicates of five seeds each were used for each treatment in both experiments. Treatments were arranged in a completely randomized design. Data were normalized by the square root transformation (y) before ANOVA analysis, and percentages were arcsin (sqrt) transformed (y). Treatment means were separated by the Tukey’s test at 5% probability using the statistical software Sisvar (Ferreira, 2014).

**Results**

**Experiment I: In vitro germination and seedling growth from cryopreserved seeds.** After cryopreservation, the best in vitro germination results were observed with jatropha seeds that were submitted to no cryoprotectants (T1) or to sucrose 0.4 M and PVS2 (T6), with 29.2% and 25% germination after seven days of in vitro culture, respectively (Table 1). However, no significant differences were observed between those treatments during this first evaluation. In addition to germination, these results were the best for seedling development, showing higher values for G, SL, RL, and NR (Table 1). By contrast, T3, T4, T5, and T9 showed lower germination percentages and poor seedling establishment in vitro (Table 1). Contamination had a significant effect on those treatments. Oxidation of seedlings was observed only in T7. However, that did not affect germination and seedling development (Table 1).

Despite the faster growth of seedlings observed 7 DAS from intact seeds (control) and from treatment T8, only the latter

Discussion

Experiment I: In vitro germination and seedling growth from cryopreserved seed.

Although cryopreservation of plant material in the form of seeds and zygotic embryos is currently widely used (Kaviani, 2011; Nadarajan and Pritchard, 2014; Silva et al., 2012), even the best treatments in this study resulted in low percentage of germination in vitro 7 DAS (T1 and T6) and 14 DAS (T1 and T8), varying between 25% and 37.5%. This could be related to intrinsic traits of the seed, such as composition, moisture content, and tolerance to ultralow temperatures (Chmielarz, 2009; Das Bhomwet al., 2011; Prada et al., 2015; Salomão et al., 2016).

Rathmani and Sivaraj (2013) emphasizes that the viability of orthodox seeds can be maintained by drying the seeds and storing at low temperatures, and jatropha shows orthodox seed storage behavior. Nonetheless, lipids present in the seed composition may make the seeds more sensitive to freezing in LN (Das Bhomwet al., 2011; Salomão et al., 2016), as observed in this study. However, Chmielarz (2009) reports that oil seeds containing unsaturated fatty acids in its composition, such as jatropha, may have the negative effect of the transition phase during freezing attenuated. Nonetheless, cryopreservation has been indicated as an efficient conservation method for different lipid and not long-lived seeds (Michalak et al., 2013; Nadarajan and Pritchard, 2014; Prada et al., 2015).

For any cryopreservation protocol, success is determined by the recovery of viable propagules (Reed, 2008) and both oxidation and contamination can be relevant issues for the survival of seedlings in vitro. In this study, seedlings originated from seeds pre-treated with sucrose 0.4 M (20 min) + PVS2 + phloroglucinol 1% (10 min) showed some oxidation symptoms in vitro (16.7%) 7 DAS, but symptoms were reversed throughout the in vitro growth time, and no oxidized material was observed at 14 DAS. However, a significant percentage of contamination in vitro caused by fungus was observed 7 DAS for T3, T4, T5, and T9, and 14 DAS for T1, T3, T4, T5, and T9. Similarly, Salomão et al. (2016) reported significant reduction in percentages of jatropha seeds germination after exposure to LN, such as 48% (whole seeds) and 57% (excised embryonic axes), being this attributed to fungal contamination.

This indicates that further studies are needed to improve sterilization procedures in protocols with cryoprotectants, which could reduce the contamination percentage in vitro, and subsequently death of plant material.
At the end of 14 d of in vitro culture, treatment T8, comprised glycerol 2 m (20 min) + sucrose 0.4 m (20 min) + PVS2 (10 min) was the most efficient for jatropha development in vitro, providing the best results for all variables. Similarly, Prada et al. (2015) reported that jatropha development was higher when embryos were pretreated with a mixture of cryoprotectants, including sucrose 0.3 m and PVS2.

Benson and Bremner (2004) consider that sugars, such as sucrose, have been regarded as vitrification agents without causing toxicity to plant cells. Our results confirmed that the addition of sucrose with glycerol and PVS2 provided proper cryoprotection to the jatropha seeds. This indicates a potential synergistic effect of sucrose with glycerol and PVS2, which resulted in a successful vitrification process. It is also likely that the cryoprotectants acted by replacing water, changing the nonpenetrating freezing behavior of the charge solution by osmotically dehydrating the cellular interior. Subsequently, the reduced temperature restricted the mobility of the water molecules inside the cell, preventing the nucleation of ice crystals (Reed, 2008) and promoting better responses in vitro, as demonstrated in this study.

By contrast, despite the previous reports of phloroglucinol as an efficient cryoprotectant to enhance germination of orchids seeds and recovery of orchid protocorms (Galdiano et al., 2012, Vendrame and Faria, 2011), it did not promote such benefits for jatropha seed germination and seedling establishment in vitro in this study.

**Experiment II: Ex vitro germination and seedling growth from cryopreserved seeds.** In the present study, seed germination percentage was higher in organic substrate compared with in vitro germination. Similar results were reported by Prada et al. (2015), who highlighted that the development of jatropha seeds after cryopreservation was 100% in sand substrate with seedlings measuring 194 mm in length, compared with 86.6% and 28 mm in length in vitro seedlings.

In this study, the use of sucrose as cryoprotectant apparently caused toxicity to plant cells, resulting in no germination and seedling development. However, sucrose has been effective to increase osmotic and colligative effects, i.e., reducing osmotic potential, leading to a reduction in the water content of cells to confer dehydration, freezing tolerance, or both (Benson and Bremner, 2004).

Either seeds nontreated (T1) or pretreated with glycerol 2 m, sucrose 0.4 m, PVS2, and phloroglucinol 1% (T9) presented good results for cryopreservation of jatropha seeds without cryoprotectants for further faster germination in organic substrate under greenhouse conditions. This behavior may also be related to the classification of J. curcas, in terms of conservation because this species is considered orthodox (Radhamani and Sivaraj, 2013) and typically could maintain its viability by drying the seeds and storing at low temperatures.
