Abstract

We study a model for the evolutionarily stable strategy (ESS) used by biological populations for choosing the time of life-history events, such as migration and breeding. In our model we accounted for both intra-species competition (early individuals have a competitive advantage) and a disturbance which strikes at a random time, killing a fraction $1 - p$ of the population. Disturbances include spells of bad weather, such as freezing or heavily raining days. It has been shown in [23], that when $p = 0$, then the ESS is a mixed strategy, where individuals wait for a certain time and afterwards start arriving (or breeding) every day. We remove the constraint $p = 0$ and show that if $0 < p < 1$ then the ESS still implies a mixed choice of times, but strong competition may lead to a massive arrival at the earliest time possible of a fraction of the population, while the rest will arrive throughout the whole period during which the disturbance may occur. More precisely, given $p$, there is a threshold for the competition parameter $a$, above which massive arrivals occur and below which there is a behaviour as in [23]. We study the behaviour of the ESS and of the average fitness of the population, depending on the parameters involved. We also discuss how the population may be affected by climate change, in two respects: first, how the ESS should change under the new climate and whether this change implies an increase of the average fitness; second, which is the impact of the new climate on a population that still follows the old strategy. We show that, at least under some conditions, extreme weather events imply a temporary decrease of the average fitness (thus an increasing mortality). If the population adapts to the new climate, the survivors may have a larger fitness.

*The first two authors contributed equally to this work.
1 Introduction

Proper timing of life-history events, like emergence, germination, migration or breeding, is crucial for survival and successful reproduction of almost all organisms. Timing may be set by endogenous rhythms or by extrinsic environmental clues (e.g. day length or temperature, \[40\]), but in almost all cases timing seems to have evolved according to two contrasting selective pressures. On the one hand, the first individuals that emerge or arrive at a given site often perform better, because they can profit from the better habitats and benefit from reduced competitions (at least for some time). On the other hand, however, early individuals may suffer from higher mortality, as they expose themselves to the risk of adverse environmental conditions, which usually are more likely early than late in the season. Autumn migration may seem an exception to this pattern, as the risk of mortality is probably larger for late than early departing individuals. However, in this case, migrants may benefit from a longer stay in their breeding grounds (allowing to rise a further brood or acquire larger fat reserves for migration). At the end, this pattern can be seen as the exact reverse of the process going on in spring, and can therefore be modelled in the same way.

In a seminal work Iwasa and Levin \[23\] have provided a first theoretical description of how the risk of incurring in adverse environmental conditions may shape the timing of life history events of a population, as a result of evolution over many generations. Under the assumption that adverse conditions (\textit{disturbance} according to their definition, which we will follow hereafter) strike at a random time and are so strong that no individual incurring in the disturbance can survive, the authors show that (in many cases) the evolutionarily stable strategy (ESS from here on) is an asynchronous choice of times in the population. This asynchronicity has been observed in various settings and modelled by several authors (see \[9\], \[11\], \[36\], \[37\], \[39\] just to mention a few). In this paper we extend Iwasa and Levin’s model to the broader scenario where the disturbance is \textit{soft}, meaning that it kills each individual with probability \(1 - p\) (in many cases some individuals in the population survive even to dramatic adverse conditions). The model of Iwasa and Levin can be seen as a particular case of ours when \(p = 0\).

Before going into the details of our model, we have to mention that it focuses on the long time behaviour of a very large population. Indeed it is implicitly assumed that when the existence of mutants with better fitness is theoretically possible, then such mutants will appear and spread across the population. This does not take into account the disappearance (in finite populations) of certain alleles by mere random factors, a phenomenon which can be studied by means of mathematical population genetics (see for instance \[18\]). Long time behaviour of finite populations can also be studied through spatial models, namely \textit{interacting particles systems}. Space not only adds
complexity [17], but may also be interpreted as “type”, that is the location of one or more individuals can be seen as representing their genotype. For the simplest among this models, the branching random walk, much has been done: for instance in [4, 5, 7, 32, 45, 47] one finds characterization of the persistence/disappearance of genotypes (seen as locations for the model), on general space structures; the same can be found, for some random graphs, in [8, 35]. Stochastic modelling and interacting particle systems have been successfully applied to biology and ecology (see [1, 2, 3, 12, 13, 24, 25, 26, 28, 19, 48] just to mention a few). Although stochastic modelling is very interesting and complex, here we will assume that over many generations, our populations have been sufficiently large to justify the use of a model where stochasticity appears only in the random time at which the disturbance strikes.

As for terminology, in the present work the life-history events under study are arrival times, meaning that we focus on migratory birds and the time of arrival to their breeding grounds. This choice of words should not be considered a reduction in the scope of this paper, since our modelling approach is very broad, as it applies to the investigation of the timing of any life-history event when the benefits from being early and the risk of incurring in a soft disturbance are in conflict. Migratory birds are a well studied biological system where timing is crucial for the fitness of individuals, and where a long record of adverse conditions killing or impairing the reproduction of individuals exists (see e.g. [33]). Moreover the interest in the timing of these recurrent biological events is very strong among biologists after that several studies have consistently observed an advancement in arrival and reproduction of birds supposedly as a consequence of climate change (see [10], [15], [46]). Climate change not only implies warming temperatures, but also higher frequency and intensity of extreme meteorological events (see [21]). This increased weather unpredictability may severely affect migrant birds, because warmer springs prompt birds towards earlier arrivals, while more frequent unseasonable weather increases the risk of mass mortality events (see [42] for a stochastic model for random catastrophes striking a spatially structured population). It is widely accepted that climate change is endangering migrant populations (see [41]). Ornithologists therefore strongly need models investigating the contrasting forces affecting the timing of bird migration to improve their understating of the ongoing ecological processes and to plan better conservation strategies for declining migrant populations. We point out that even if our primary interest here are evolutionarily stable strategies which arise in large populations after many generations of stable climate (an equilibrium situation), our study also allows us to analyze some effects of a sudden climate change (an off-equilibrium dynamics). Indeed our results not only describe the ESS (Theorem 3.5) but also the effects of the climate change on the fitness of a population not yet adapted to the change (Propositions 3.7, 3.8 and 3.9).

Here is a short outline of the results of the paper. In Section 2 we introduce the model and the notation. We consider an intra-species competition regulated by a parameter $a \geq 0$ and we define the fitness $\psi_\mu$ as a function of the arrival time conditioned on the disturbance time, the
expected fitness $\phi_{\mu}$ depending only on the arrival time (averaged over all admissible disturbance times) and, later on, the average fitness $\bar{\lambda}_{\mu}$ (averaged over all disturbance and arrival times). We describe the meaning of an evolutionarily stable strategy (ESS) and we discuss the easiest cases where either there is no competition ($a = 0$) or the probability $p$ of surviving the disturbance is 1, i.e. the disturbance has no effect whatsoever (Remark 2.1). Section 3 contains our main results. Theorem 3.5 extends [23, Appendix A] and shows that there is only one possible ESS for the population in response to a fixed disturbance distribution, which we imagine supported in $[t_f, t_f]$. The behaviour of the ESS depends on the value of $(a, p)$. Indeed there exists a function of $p$, say $a_M = a_M(p)$, such that if $a < a_M$ then the population starts arriving after a date $x_c > t_f$ and there are arrivals every day until $t_f$; if $a = a_M$ then continuous arrivals starts at $t_f$; if $a > a_M$ then a fraction $\gamma$ of the population arrives at time 0 and the rest arrives continuously starting from $t_f$. The dependence on $a$ and $p$ of the fitness of individuals following the ESS is discussed; in particular we show (see Remark 3.6) that the theoretical maximum value of the average fitness $\bar{\lambda}_{\mu}$ is not attained by any ESS. This proves that, even though an ESS is a strategy that each member of the colony considers fair, it is not the best choice for the colony as a whole. The dependences of every relevant coefficient on $a$, $p$ and the disturbance distribution are summarized in a table before the beginning of Section 3.1. As an example, we describe the case where the disturbance strikes according to a uniform distribution (see Section 3.1). The effects of climate changes are studied in Section 3.2. The main questions discussed here are the following. How does the ESS change after a climate modification? What happens if a population would keep the same strategy after a climate change? A worse climate, that is a smaller $p$, may change the shape of the ESS delaying the first arrivals and increasing the fitness of each individual (provided that the population survives the transition). If the distribution of the disturbance is linearly rescaled, the same happens to the ESS. The behaviour of the fitness, before the strategy adapts, is studied in Propositions 3.7, 3.8 and 3.9. A consistent delay of the disturbance reduces the fitness of all individuals following the former ESS. If the disturbance arrives earlier than in the past, then the average fitness of the population increases. When the competition is weak then a decrease of $p$ implies a killing of a larger fraction of the population and hence a lower average fitness. In Section 4 we discuss and summarize the conclusion of the paper. Section 5 is devoted to the proofs of our results.

2 The model

Iwasa and Levine [23] studied different ways to model the fact that individuals choosing an early date of arrival, if no disturbance were present, would obtain a larger fitness than those arriving later. This may be due to the fact that a decrease of reproductive success (better resources at earlier times, [23 Case 1]) or to competition between individuals, for instance those who arrive earlier may feast on food, while those arriving later will not ([23 Case 2]). We focus on the second
case, where Iwasa and Levin proved the emergence of a mixed strategy for the arrival dates (which is more interesting and realistic than Case 1, where all individuals choose the same date).

Suppose that $\mu$ is the probability measure, supported on $[0, +\infty)$, according to which individuals choose the date of arrival to the breeding sites. Its cumulative distribution function $F_\mu$ is defined, as usual, by $F_\mu(x) := \mu((-\infty, x])$ for all $x \in \mathbb{R}$. The population is struck by a single disturbance (e.g. storm, frost) whose date is randomly distributed on $(t_f, \bar{t}_f)$ with density $f$. It may be that $t_f = 0$ ($t_f$ is the first possible date of disturbance while $\bar{t}_f$ is the last). Individuals already present when the disturbance occurs, survive with probability $p \in [0, 1]$. The fitness of an individual is a decreasing function of the fraction of individuals (in the whole population) who are already present when it arrives, and of the parameter $a \geq 0$ which represents the strength of intra-species competition. Inspired by \cite{23} we choose the following expression for the fitness $\psi_\mu$ of an individual arriving at date $y$, given that the disturbance strikes at time $x$:

$$
\psi_\mu(y|x) = \begin{cases} 
p \exp(-aF_\mu(y)) & \text{if } 0 \leq y \leq x; \\
\exp(-apF_\mu(x) - aF_\mu(y) + aF_\mu(x)) & \text{if } y > x.
\end{cases}
$$

Thus $\psi_\mu(y|x)$ is the fitness (under the strategy $\mu$) of an individual arrived at time $y$ when the disturbance strikes at time $x$. It is worth noting that we are implicitly exploiting the Law of Large Numbers (LLN), since the exact value of $\psi_\mu(y|x)$, for instance if $y \leq x$, is

$$
\psi_\mu(y|x) = p \exp(-aN(y)/N),
$$

where $N(y)$ is the random number of individuals arrived before $y$ and $N$ is the population size. If $N$ is large, the LLN implies that $N(y)/N$ can be approximated by $F_\mu(y)$. Similarly one proceeds with the case $y > x$.

We consider the expectation of the fitness, with respect to the disturbance date: the expected fitness of an individual arrived at $y$ is

$$
\phi_\mu(y) = \int_0^y \psi_\mu(y|x) f(x) dx.
$$

More explicitly, for $y \geq 0$,

$$
\phi_\mu(y) = \exp(-aF_\mu(y)) \left[ \int_0^y \exp(a(1-p)F_\mu(x)) f(x) dx + p \int_y^{t_f} f(x) dx \right] = \exp(-aF_\mu(y)) \left[ \int_0^y (\exp(a(1-p)F_\mu(x)) - p) f(x) dx + p \right]
$$

(2.1)

We note that, in the last integral of equation (2.1) (as well in every integral of a function of type $k(x)f(x)$ in the sequel), one could use $+\infty$ instead of $\bar{t}_f$ and the value of the integral would be the same (as the definition of $\phi_\mu$); moreover if $y > \bar{t}_f$, by $\int_y^{\bar{t}_f}$ we mean $-\int_{\bar{t}_f}^y$. 

5
We assume that, the population follows evolutionarily stable strategies, that is, distributions of arrival times which grant no advantage to any particular choice of arrival date. More precisely, an evolutionarily stable strategy (ESS) $\mu$, is such that no mutant can have an advantage, namely for all $y \in \text{supp}(\mu)$ and for all $z \in \mathbb{R}^+$, $\phi_\mu(y) \geq \phi_\mu(z)$. This implies that $\phi_\mu(y) = \lambda$ for all $y \in \text{supp}(\mu)$, where $\lambda := \sup\{\phi_\mu(y): y \in \mathbb{R}^+\} \leq 1$. We recall that $\text{supp}(\mu)$ is the (closed) set of $y$ such that $\mu(y - \varepsilon, y + \varepsilon) > 0$ for all $\varepsilon > 0$. We will also need to define the essential support $\text{Esupp}(f)$ of a real function $f$, which is the support of the associated measure $A \mapsto \int_A f(x)dx$ (for instance, if $f$ is continuous then $\text{Esupp}(f) = \{f \neq 0\}$). We recall that in [23] the probability distribution of the disturbance was considered as absolutely continuous with a single peak density $f$ which was taken, on $[0, t_f]$ as a polynomial vanishing at the extrema of the interval. We only assume that $f$ is a probability density, supported in $[0, t_f]$. From now on, without loss of generality, we assume $t_f := \max \text{Esupp}(f)$ and $t_f := \min \text{Esupp}(f)$.

We are interested in studying $\mu$ as a function of $a$ and $p$ (and of $f$, but here $f$ is thought as fixed). The extremal cases where either $a = 0$ or $p = 1$ are easy to describe.

**Remark 2.1.**

1. If $a = 0$ and $p = 1$, there is no competition and the disturbance has no effect. Then $\phi_\mu(y) = 1$ for all $y > 0$; moreover, every $\mu$ is an ESS (indeed the disturbance has no chance to shape an evolutionary response of the species).

2. If $a = 0$ and $p < 1$, there is no competition. From equation (2.1) we have, $\phi_\mu(y) = 1 - (1 - p) \int_y^{t_f} f(z)dz$ which is non decreasing and continuous and $\phi_\mu(y) = 1$ for all $y \geq t_f$. We see here that there is no dependence on $\mu$. A probability measure $\mu$ is thus an ESS if and only if $\text{supp}(\mu) \subseteq [t_f, \infty)$. This means that all individuals will arrive after the last possible date of disturbance.

3. If $a > 0$ and $p = 1$, there is competition and the disturbance has no effect. From equation (2.1) we have $\phi_\mu(y) = \exp(-aF_\mu(y))$ which is right-continuous and nonincreasing. Using the same arguments as in the proof of Theorem 3.5 it is straightforward to prove that there is a unique ESS, namely $\mu = \delta_0$. Everybody arrives at the first possible arrival date (indeed there is no risk in doing so).

4. If $a > 0$ and $p = 0$, the case has been studied in [23, Case 2] and can be retrieved as a particular case of Theorem 3.5. There exists a critical date $x_c$ (depending on $a$ and $f$) after which individuals start arriving according to an absolutely continuous measure $\mu$ such that $\text{supp}(\mu) = (x_c, t_f)$. The expected fitness of each individual is $\lambda = \frac{1}{1+a}$.

The interesting case is when $a > 0$ and $p < 1$, that is, competition in the population and effective disturbance. These are the constraints which we assume thereafter.
3 Main result

We are able to prove (Theorem 3.5) that given \( p < 1 \), there exists a critical \( a_M \), depending only on \( p \) (not on \( f \)) such that:

1. if \( a < a_M \) then the ESS is as follows: there is a critical date \( x_c > t_f \) (depending on \( a, p \) and \( f \)) after which individuals arrive continuously while disturbances are possible (see for instance Figure 5). This extends the previously known result for \( p = 0 \) since \( a_M(0) = +\infty \) (see [23, Case 2]);

2. if \( a = a_M \) then the ESS is as before, with \( x_c = t_f \) (individuals arrive throughout the whole period of possible disturbance, see for instance Figure 6);

3. if \( a > a_M \) then the ESS is such that a fraction \( \gamma \) of individuals arrive at 0, and the remaining arrive continuously during the whole period of possible disturbance (see for instance Figure 7).

Before stating our main result, we define the quantities \( a_M, x_c \) and \( \gamma \).

**Definition 3.1.** If \( p = 0 \), then \( a_M(p) := +\infty \); if \( p \in (0,1) \), then \( a_M(p) \) is the solution to the equation

\[
\int_1^{\exp(a_M)} \frac{dz}{z^{1-p} - p} = \frac{1}{p}.
\] (3.2)

Note that the solution to equation (3.2) exists and is unique since the l.h.s. is a continuous, strictly increasing function of \( a_M \) which vanishes at \( a_M = 0 \) and goes to infinity as \( a_M \to \infty \). The inverse function of \( a_M \) will be denoted by \( p_M(a) \) (by definition \( p_M(+\infty) := 0 \)). Clearly \( a \leq a_M(p) \) (resp. \( a \geq a_M(p) \)) if and only if \( p \leq p_M(a) \) (resp. \( p \geq p_M(a) \)).

**Definition 3.2.** If \( a > a_M(p) \) let \( x_c = x_c(a,p,f) \) := 0. If \( a \leq a_M(p) \) define \( x_c \) as the maximal solution to the equation

\[
\int_{x_c}^{t_f} f(x)dx = \left(1 - p + \left(\int_1^{\exp(a)} \frac{dz}{z^{1-p} - p}\right)^{-1}\right)^{-1}.
\] (3.3)

Note that the solution to equation (3.3) exists and is unique, since the r.h.s. is positive and strictly smaller than 1, while the l.h.s. is a continuous, nonincreasing function of \( x_c \) which takes values 1 and 0 at \( x_c = 0 \) and \( x_c = t_f \) respectively. By definition if \( a \leq a_M(p) \), \( x_c \in \text{Esupp}(f) \).

**Definition 3.3.** If \( a \leq a_M(p) \) let \( \gamma = \gamma(a,p) \) := 0. If \( a > a_M(p) \) let \( \gamma \) be the unique solution to the equation

\[
\exp(-a\gamma) \int_{\exp(a\gamma)}^{\exp(a)} \frac{dz}{z^{1-p} - p} = \frac{1}{p}.
\] (3.4)
The solution exists and is unique since the l.h.s. is a continuous, strictly decreasing function of \( \gamma \) which takes values in \((1/p, +\infty)\) when \( \gamma = 0 \) and is equal to 0 when \( \gamma = 1 \). Observe that \( \gamma(a, 0) = 0 \) for all \( a > 0 \).

Note that, in accordance with [23], if \( p = 0 \) then \( a_M = +\infty \), \( \gamma = 0 \), and \( \int_{x_c} f(x) dx = a/(1 + a) \).

Let us discuss some general properties of \( a_M \), \( x_c \) and \( \gamma \). For details on the proofs, see Section 5.

**Remark 3.4.**

1. The map \( p \mapsto a_M(p) \) is continuous and strictly decreasing; see Figure 1. By using elementary techniques of implicitly defined functions it is not difficult to prove that 
   \[
   \lim_{p \to 0^+} a_M(p) = +\infty, \quad \lim_{p \to 1^-} a_M(p) = 0.
   \]

2. Given a fixed \( f \), we have that \( p \mapsto x_c \) and \( a \mapsto x_c \) are strictly decreasing and left continuous everywhere. The map \( p \mapsto x_c \) is right continuous at \( p_0 \) only in the following cases: (a) \( a > a_M(p_0) \); (b) \( a < a_M(p_0) \) and \( (x_c(a, p_0, f) - \varepsilon, x_c(a, p_0, f)) \subseteq \text{Esupp}(f) \) for some \( \varepsilon > 0 \); (c) \( a = a_M(p_0) \) and \( t_f = 0 \). Similarly \( a \mapsto x_c \) is right continuous at \( a_0 \) only in the cases: (a) \( a_0 > a_M(p) \); (b) \( a_0 < a_M(p) \) and \( (x_c(a_0, p, f) - \varepsilon, x_c(a_0, p, f)) \subseteq \text{Esupp}(f) \) for some \( \varepsilon > 0 \); (c) \( a_0 = a_M(p) \) and \( t_f = 0 \). Again using standard techniques of implicitly defined functions we have
   \[
   \lim_{p \to 0^+} x_c(a, p, f) \leq x_c(a, 0, f) < t_f = \lim_{a \to 0^+} x_c(a, p, f); \quad \lim_{p \to p_M(a)^-} x_c(a, p, f) = t_f = \lim_{a \to a_M(p)^-} x_c(a, p, f). \tag{3.5}
   \]

3. The function \( (a, p) \mapsto \gamma(a, p) \) is continuous on \((0, +\infty) \times [0, 1)\) and \( p \mapsto \gamma(a, p) \) is strictly increasing (for all fixed \( a \in (0, +\infty) \)). Moreover \( \gamma(a, p) < p \) for all \( p \in (0, 1) \) and for all \( a > 0 \); \( a \mapsto \gamma(a, p) \) is strictly increasing in \([a_M(p), +\infty)\) for all fixed \( p \in (0, 1) \) (see Remark 5.3). See Figures 2 and 3 for some plots of \( p \mapsto \gamma(a, p) \) and \( a \mapsto \gamma(p, a) \). Moreover, we have
   \[
   \lim_{p \to 0^+} \gamma(a, p) = 0, \quad \lim_{p \to 1^-} \gamma(a, p) = 1, \quad \lim_{a \to +\infty} \gamma(a, p) = p,
   \]
   where the last limit holds for all \( p > 0 \).
Theorem 3.5. Let $a_M$, $x_c$ and $\gamma$ be as previously defined. Given $a > 0$, $p \in [0,1)$ and $f$ a probability density supported in $[0,\bar{t}_f]$ (where by definition $\bar{t}_f = \max \text{Esupp}(f)$), there exists a unique ESS $\mu$. In particular, $\mu = \gamma \delta_0 + (1 - \gamma) \nu$, where $\nu$ is an absolutely continuous probability measure with $\text{supp}(\nu) = [x_c, \bar{t}_f] \cap \text{Esupp}(f)$. The cumulative distribution function $F_\nu$ is implicitly defined, on $x \geq x_c$, by

$$
\int_{\exp(a\gamma)}^{\exp(a(1-\gamma)F_\nu(x)+a\gamma)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} \int_{x_c}^x f(y)dy. \quad (3.6)
$$

The value of $\lambda$ (the supremum of $\phi_\mu$) is

$$
\lambda = \lambda(a,p) = \begin{cases} 
1 & \text{if } a \leq a_M \\
1 + (1 - p) \int_1^{\exp(a)} \frac{dz}{z^{1-p} - p} & \text{if } a > a_M 
\end{cases} \quad (3.7)
$$
Finally, \( a_M \) is a phase transition value for the competition in the sense that

\[
\begin{align*}
a < a_M & \implies \gamma = 0, \; x_c > t_f; \\
a = a_M & \implies \gamma = 0, \; x_c = t_f; \\
a > a_M & \implies \gamma \in (0, (1 - a_M/a) \land p), \; x_c = 0.
\end{align*}
\]

It is worth noting that, in equation (3.6), we can write \( F_\mu(x) \) instead of \( \gamma + (1 - \gamma)F_\nu(x) \).

Several features of the ESS \( \mu \) can be read from Theorem 3.5. Beside arrivals at 0 (possible only when competition is sufficiently strong), individuals arrive only at possible disturbance dates. This means that if it is certain that during \( [s, t] \subset [t_f, \bar{t}_f] \), no disturbance is possible (i.e. \( f(x) = 0 \) for all \( x \in [s, t] \)), then the probability of arrivals in such interval is zero. This is due to competition, which advantages early birds: there is no point in choosing to arrive in between \( s \) and \( t \), since there is no risk in choosing \( s \) instead.

In most real cases, one may assume that \( f > 0 \) on \( [0, t_f] \). In that case individuals will arrive either (1) avoiding the first part of the possible time period (weak competition, see Figure 16) or (2) during the whole interval \( [0, \bar{t}_f] \) without massive arrivals at 0 (critical competition, Figure 15) or (3) during the whole interval with massive arrivals at 0 (supercritical competition, Figure 14).

The first arrival time \( x_c \) is strictly decreasing with respect to \( p \) and to \( a \) (Remark 3.4); this means that strong competition and/or high probability of surviving the disturbance, push arrivals to 0. If \( p \) is fixed, competition needs to be above the threshold \( a_M(p) \), in order to have arrivals at 0. On the other hand, if competition is fixed, only weak disturbances lead to early arrivals.

As for \( \gamma \), the fraction of arrivals at 0, we know that it increases with \( p \). If \( p > 0 \), from equation (3.6), using \( \gamma(a, p) \uparrow p \) as \( a \to \infty \), it follows that \( F_\nu(x) \to 1 \) for all \( x \in (\bar{t}_f, \bar{t}_f] \) as \( a \to \infty \). This means that, as the competition increases, given that an individual does not arrive at time 0 (this probability converges monotonically to 1 from above) then the probability of arriving after \( x > \bar{t}_f \) goes to 0, that is, in the limit as \( a \to \infty \) the arrival distribution converges to \( p\delta_0 + (1 - p)\delta_{\bar{t}_f} \) (that is, \( \delta_0 \) if \( \bar{t}_f = 0 \)). Note that this does not happen when \( p = 0 \): in that case \( F_\nu(x) = \frac{1 + \alpha}{a} \int_{x_c}^{t_f} f(y) \, dy \) which implies that \( F_\nu \) converges to the cumulative distribution of the disturbance arrival time.

Associated to a given strategy \( \mu \), there is the average fitness \( \bar{\lambda}_\mu := \int_0^{+\infty} \phi_\mu(y) \mu(dy) \). In particular when \( \mu \) is an ESS, then \( \phi_\mu(y) = \lambda \) for all \( y \in \text{supp}(\mu) \) (where \( \lambda = \lambda(a, p) \), see (3.7)), hence \( \bar{\lambda}_\mu = \lambda(a, p) \). If \( a \leq a_M \) we can relate \( \lambda(a, p) \) to \( x_c \): by equations (3.3) and (3.7) we have

\[
\int_{x_c}^{t_f} f(y) \, dy = \frac{1 - \lambda(a, p)}{1 - p} = \lambda(a, p) \int_1^{\exp(a)} \frac{dz}{z^{1-p} - p}. \tag{3.8}
\]
It is not difficult to prove that \((a, p) \mapsto \lambda(a, p)\) is continuous in \((0, +\infty) \times [0, 1)\); moreover \(a \mapsto \lambda(a, p)\) and \(p \mapsto \lambda(a, p)\) are strictly decreasing functions (see Remark 5.3) such that

\[
\lim_{a \to 0^+} \lambda(a, p) = 1, \quad \lim_{a \to +\infty} \lambda(a, p) = 0;
\]
\[
\lim_{p \to 0^+} \lambda(a, p) = \frac{1}{1 + a}, \quad \lim_{p \to 1^-} \lambda(a, p) = \exp(-a),
\]

hence \(\lambda(a, 0) = (1 + a)^{-1} \geq \lambda(a, p) \geq \exp(-a) = \lambda(a, 1)\) for all \(p \in [0, 1]\); moreover \(\lambda(a_M(p), p) = p\).

Thus, when \(\mu\) is an ESS the average fitness \(\bar{\lambda}_\mu = \lambda(a, p)\) is decreasing with respect to \(p\) (when \(a > 0\)), hence, if we think of the fitness as a probability of survival, the average rate of survivors is decreasing if the chance of surviving the catastrophe \(p\) is increasing. From a biological point of view, this model suggests that, in the presence of competition, if the disturbance is weaker (that is, \(p\) increases) then the ESS pushes the colony towards an early arrival on the site, increasing the negative effects of the competition on the fitness (which overcome the positive effects of the weaker disturbance). Hence the stronger the disturbance the higher the average fitness corresponding to the ESS (in some sense, if we think of the average fitness of the population as its “strength”, a strong disturbance will select a stronger population).

One may wonder if there are strategies \(\mu\) which (given the environment \((a, p, f)\)) lead to a larger \(\bar{\lambda}_\mu\), and whether these strategies are Evolutionary Stable Strategies.

**Remark 3.6.** The supremum of the map \(\mu \mapsto \int \phi(\nu(y)\mu(dy) = \bar{\lambda}_\mu\) is \((1 - \exp(-a))/a\) and is attained by \(\mu\) if and only if \(\inf \text{supp}(\mu) \geq \sup \text{Esupp}(f) = \bar{t}_f\) and \(F_\mu\) is continuous (and this supremum holds for any fixed \(p\), see details in Section [3]). This means that the best choice for the population as a whole, is to start arriving after the last possible date of disturbance. In particular no ESS can attain this maximum value (an ESS is supported in \([0, \bar{t}_f)\)). An ESS is a strategy which is
well accepted by every individual (since the fitness is constant and maximal), while the maximizing strategies imply that some individuals “accept” a lower fitness for the benefit of the whole colony (note that the continuity of $F_\mu$ implies that the population cannot choose to arrive simultaneously at $T_f$, which would guarantee the same fitness for everyone). Moreover, even if the maximal fitness is attained only arriving after $T_f$, it is possible to prove that we can find a sequence of strategies (not ESSs) $\{\mu_n\}_{n \geq 1}$, supported in $[0, T_f]$ such that $\bar{\lambda}_{\mu_n} > \left(1 - \exp(-a)/a - 1/n\right)$. In Figure 4 the dashed line represents $\sup_{\mu} \bar{\lambda}_{\mu}$, whereas the dotted and the solid ones are the average fitness when the population follows the ESS, $\lambda(a,1)$ and $\lambda(a,0)$, respectively. The filled region represents all possible values for $\lambda(a,p)$ with $p \in (0, 1)$. Note that following the ESS a population cannot achieve the maximal average fitness, nevertheless if $a$ is either small or large, then the dashed and the solid line are close, hence, if $p = 0$ or at least $p$ is small, then the average fitness is not so far from its theoretical supremum.

![Figure 4: Maximum average fitness and the admissible region for $\lambda(a,p)$.

In the following table, we summarize the main properties of the coefficients $a_M$, $\gamma$, $\lambda$ and $x_c$; by $\nearrow x$ and $\searrow x$ we mean that a particular coefficient is increasing or decreasing with respect to the parameter $x$.}
Given \((a, p, f)\), Theorem 3.5 gives the unique ESS \(\mu\) and its average fitness \(\lambda\). We note that the map \((a, p, f) \mapsto (\lambda, \mu)\) is not injective. Indeed, at least when \(a \leq a_M(p)\), it might be that \(\lambda(a, p) = \lambda(b, q)\) for some \(q\) and \(b\). Even if we fix \((a, p)\), at least in the subcritical case, different disturbance distributions may lead to the same ESS. Indeed, suppose that \(a < a_M(p)\) then \(x_c > 0\) and \(\gamma = 0\). Given \(\mu\) is fixed, from equation (3.6), \(f\) is uniquely determined on \([x_c, \bar{t}_f]\). Nevertheless, on \([0, x_c]\) the only constraint is \(\int_0^{x_c} f(x)\,dx = (p - \lambda)/(1 - p)\), which can be satisfied by infinitely many distributions. This means that different levels of competition, and/or of climate, can lead to the same response \(\mu\) and same fitness \(\lambda\).

### 3.1 Uniformly distributed disturbances

In this example we suppose that \(f(t) = (\bar{t}_f - t_f)^{-1} \mathbb{1}_{[t_f, \bar{t}_f]}(t)\), that is, the law of the disturbance is uniformly distributed in the interval \([t_f, \bar{t}_f]\) (we also write \(f \sim \mathcal{U}(t_f, \bar{t}_f)\)). In this case some explicit computations are possible.

The coefficients \(a_M, \lambda, \gamma\) do not depend of \(f\); the only coefficient depending on \(f\) is the first time of arrival \(x_c\) (which is nonzero only if \(a \leq a_M\)). If \(a \leq a_M\), then

\[
x_c = t_f + \alpha(a, p)(\bar{t}_f - t_f)
\]

where \(\alpha(a, p) := \frac{1 - p C(a, p)}{1 + (1 - p) C(a, p)}\), with \(C(a, p) = \int_1^{\exp(a)} \frac{dz}{z^{1-p} - p} \leq 1/p\). This means that, in the subcritical case, the ratio \(R\) between the length of the arrival times interval and that of the disturbance times interval, depends only on \(a\) and \(p\) (not on \(f\)); indeed

\[
R := \frac{(\bar{t}_f - x_c) / (\bar{t}_f - t_f)}{(1 - p + C(a, p)^{-1})^{-1}}.
\]

The cumulative distribution function \(F_\mu\) can be computed using equation (3.6). Although when \(p \neq 0\) no explicit evaluations are possible, one can see that \(F_\mu\) is a rescaling of the cumulative distribution function of the ESS obtained when the disturbance is uniformly distributed on the interval \([0,1]\) (with the same parameters \(a\) and \(p\)), which we denote by \(F_0^{a,p}\). More precisely, if
$F_\nu = F_{a,p}^{\alpha}$ is the cumulative distribution function of the ESS when $f \sim U(t_f, \bar{t}_f)$, then

$$F_{\nu}^{a,p}(x) = F_0^{a,p}\left(\frac{x - t_f \lor x_c}{\bar{t}_f - t_f \lor x_c}\right)$$

(3.9)

(recall that $t_f \lor x_c = x_c$ if $a < a_M$ while $t_f \lor x_c = t_f$ if $a \geq a_M$). Using computer-aided numerical solutions, in Figures 3-10 we plot the cumulative distribution functions of the ESS (solid line) and of the disturbance (dashed), with different parameters and disturbance intervals. In the first row, Figures 5-7, we take $f \sim U(0.5, 0.9)$ while in the second row, Figures 8-10, we have $f \sim U(0.3, 1)$.

In the three figures in each row, the parameters $(a, p)$ are, respectively, $(0.2, 0.2)$, $(5, 0.2)$ and $(5, 0.5)$. This implies that the first figure represents a subcritical case ($a = 0.2 > a_M(0.2) = 3.30447$). Note that in both rows in this case the arrivals start towards the end of the disturbance intervals and the ratio between the length of the two intervals representing the arrival times and the disturbance time is the same, $R = 0.208552$.

The second figure of the row is a supercritical case ($a = 5 > a_M(0.2)$), where a fraction $\gamma = 0.10142$ of the population arrives at time 0. In both rows the fraction $\gamma$ is the same ($\gamma$ depends only on $a$ and $p$).

The third figure is again a supercritical case ($a = 5 > a_M(0.5) = 0.941046$), where strong competition forces a larger fraction of the population ($\gamma = 0.456433$) to arrive early. Along with the values of $a$ and $p$, in Figures 5-10 we write the explicit value of the maximum average fitness $\lambda$. Note that $\lambda$ increases when either $p$ decreases or $a$ increases, the maximum competition $a_M$.

As we have seen in Figures 5-10 by (3.9), it is enough to study the case $f \sim U(0, 1)$. In
Figures 11-19 we plot the cumulative distribution function $F_{a,p}^0$ (solid line) corresponding to nine couples $(p, a)$, together with the cumulative distribution function of the disturbance (dashed line). In each row $p$ takes the same value ($p = 0.1$, 0.3 and 0.5 in the first, second and third row respectively), while $a$ is constant along each column ($a = a_M(0.1)$, $a_M(0.3)$ and $a_M(0.5)$ in the first, second and third column respectively). In this way, figures on the diagonal represent critical cases, figures on the upper triangle are subcritical cases and figures on the lower triangle are supercritical cases.

3.2 Climate changes

In our model the climate can be represented by the couple $(p, f)$, that is, the distribution and the strength of the disturbance; more precisely the lower $p$ the stronger the disturbance. One can argue that also the competition parameter $a$ could be affected by the climate, nevertheless, in this paper, we prefer to think of it as a characteristic of the population.
When climate changes (i.e. the couple \((p, f)\) changes), there are two interesting questions.

1. How does the ESS change reflects a climate change? In other words, can we predict in which respect the new ESS will differ from the previous one?

2. What happens if a colony keeps the same strategy of arrivals after a climate change? Does the average fitness of the population decrease or increase?

Some answers can be obtained if we imagine that the climate change affects just one of the parameters \(p\) and \(f\).

The answer to question 1, is given by Theorem 3.5. If \(p\) decreases, then \(\lambda(a, p)\) increases: after the population has adapted to the new climate the common fitness will have increased (of course supposing that the population is sufficiently large to survive the transition period). Moreover, a decrease of \(p\) may lead from an ESS with massive arrival at 0, to an ESS with arrivals after a date \(x_c > t_f\). Let us discuss now what happens if \(f\) changes, that is if it moves from \(f_1\) to \(f_2\). The fitness of every individual, according to an ESS adapted to \(f_i\), is \(\lambda(a, p)\) which does not depend on \(f_i\), thus that will not change in case of rapid adaptation (question 1). What will change is the distribution of the arrival times and possibly its support. In the case of uniformly distributed disturbances, the answer to question 1 is given by equation (3.9): a change of the interval during which disturbances occur is simply reflected by a rescaling of the ESS. It is worth noting that an analogous result holds if we take a generic density \(f\) defined on \([0, 1]\) and we rescale it as follows

\[
f_i(t) := f\left(\frac{t - t_f}{t_f - t_f}\right);
\]

(3.10)

the effect on the ESS in this general case is still the rescaling given by equation (3.9).

The second question is particularly interesting in the case of rapid climate changes, since the adaptation of the population (moving from the old ESS to the new one) could require several generations; thus the changes may endanger the survival of the population. A sudden change of climate may be an advantage for some individuals (i.e. some arrival dates) and a disadvantage for other individuals. Even in the case of a simple anticipation of the disturbance the situation is not trivial. Suppose that \(f_1\) is supported in \([\bar{t}_1, \bar{t}_1]\) and \(f_2\) is supported in \([\bar{t}_2, \bar{t}_2]\), with \(\bar{t}_2 < \bar{t}_1\). Individuals arriving at \(y > \bar{t}_2\) are sure that the disturbance is over but they might have more competitors still alive (for instance those arriving at \(y - \varepsilon\)), thus it is not clear whether the climate change implies a larger or smaller fitness. The following proposition gives a partial answer: let us denote by \(\phi^{(i)}(y)\) the fitness of an individual, in a population following the strategy \(\mu\) (not necessarily an ESS), which chooses the arrival date \(y\) and has to face the disturbance which is regulated by \(f_i\). If \(f_2\) is a delay of the disturbance, that is, in the second scenario disturbances strike later in the season, early birds suffer a decrease of their fitness. The second part of the proposition tells us that, at least for uniform disturbances, if \(f_2\) delays the beginning of the disturbance but also anticipates the end of the disturbance season, then later birds have an advantage.
Proposition 3.7. Consider a distribution \( \mu \) and two densities \( f_1 \) and \( f_2 \) on the intervals \([t_1, \bar{t}_1]\), \([t_2, \bar{t}_2]\).

1. If \( t_1 < t_2 \) then \( \phi^{(1)}(y) \geq \phi^{(2)}(y) \) for all \( y \in [t_1, t_2] \).

2. If \( \mu \) is the ESS associated to \( f_1 \), \( D_2 \) is a random variable with density \( f_2 \) and \( \mathbb{P}(t_2 < D_2 < \bar{t}_1) \) is sufficiently small then \( \phi^{(1)}(y) \geq \phi^{(2)}(y) \) for all \( y \in [t_1, \bar{t}_1] \).

3. If \( f_1 \) and \( f_2 \) are uniform densities and \( t_1 \leq t_2 \) and \( \bar{t}_1 \geq \bar{t}_2 \) then \( \phi^{(2)}(y) \geq \phi^{(1)}(y) \) for all \( y \geq y_1 := (t_1 \bar{t}_2 - t_2 \bar{t}_1)/(t_1 + \bar{t}_2 - t_2 - \bar{t}_1) \) (where \( y_1 \in [\bar{t}_2, \bar{t}_1] \)).

Proposition 3.7(1) and (3) follow from a more general result (Proposition 5.8) which allows to compare \( \phi^{(1)} \) and \( \phi^{(2)} \) in more general settings. Proposition 5.8 is fairly technical and can be found in Section 5. Proposition 3.7(2) implies for instance that a consistent delay of the disturbance (think of \( t_2 > \bar{t}_1 \)) reduces the fitness of all individuals following the former ESS. Even if it is not necessary that \( t_2 > \bar{t}_1 \), the requirement that \( \mathbb{P}(t_2 < D_2 < \bar{t}_1) \) is sufficiently small, implies that \( \bar{t}_2 > \bar{t}_1 \).

It is not trivial to assess whether individuals that profit from the climate change represent a small or large fraction of the population following what was a former ESS. More precisely, it is not always clear whether the average fitness \( \bar{\lambda}_\mu \) increases or not. Nevertheless it is not difficult to provide some partial answers in the case of delay or anticipation of the disturbance.

Proposition 3.8. Consider two densities \( f_1 \) and \( f_2 \) on the intervals \([t_1, \bar{t}_1]\), \([t_2, \bar{t}_2]\) and let \( \mu \) be the ESS associated to \( f_1 \). Denote by \( D_2 \) a random variable with density \( f_2 \).

1. \( \bar{\lambda}_\mu^{(2)} < \bar{\lambda}_\mu^{(1)} \) provided that \( \mathbb{P}(t_2 < D_2 < \bar{t}_1) \) is sufficiently small.

2. \( \bar{\lambda}_\mu^{(2)} > \bar{\lambda}_\mu^{(1)} \) provided that \( F_\mu(\bar{t}_2) \) is sufficiently small.

Proposition 3.8(1) implies that a consistent delay of the disturbance reduces the average fitness of the population; on the other hand, Proposition 3.8(2) implies that the average fitness of the population increases if the disturbance arrives so early that most of the population has not yet arrived when the danger is over.

Let us discuss now the consequences of a change of \( p \). In the previous sections we showed that \( p \mapsto \lambda(a, p) \) is decreasing. This means that if \( p \) decreases and there is an instantaneous adaptation of the population to the new conditions (i.e. the arrival distribution \( \mu \) changes accordingly) then the fitness of each individual (hence the average fitness) increases, because more individuals will choose to arrive later in the season. Intuitively, if the population does not adapt to the climate change, a decrease of \( p \) should imply a killing of a larger fraction of the population and hence a lower average fitness. The following result tells us that this intuition is correct, at least for weak competition.
Proposition 3.9. Given a generic arrival strategy \( \mu \), recall the definition of the average fitness as 
\[
\bar{\lambda}_\mu = \bar{\lambda}_\mu(a, p, \mu, f) = \int \phi_\mu(y) \mu(\text{d}y).
\]
The function \( p \mapsto \bar{\lambda}_\mu = \bar{\lambda}_\mu(a, p, \mu, f) \) is continuous in \([0, 1]\). Moreover for all \( a \in (0, 2 \log(2)] \) we have \( \partial_p \bar{\lambda}_\mu(a, p, \mu) \geq 0 \) for all \( p \in (0, 1) \) and the inequality is strict if and only if \( F_\mu(x) > 0 \) for some \( x < t_f \).

This means that, if the competition is low, then when the probability of surviving the disturbance decreases then the fitness decreases as well. Roughly speaking, in case of low competition it is better to arrive later (and to have more competitors) than to take a chance against the disturbance.

4 Discussion

In this paper we developed a model for the timing of life history events when a disturbance can strike a population of migrators and may kill some of the individuals that incur in it. Our model therefore considered the biologically realistic scenario of a “soft” disturbance, i.e. an event, like extreme unseasonable weather, that can kill a fraction of the population, but to which some individuals survive. We developed our study by considering migratory birds as a model, because they are biological system where the timing of life history events has been intensively studied. In particular, we looked for the ESS for individuals that have to choose arrival time to their breeding grounds, and benefit from early arrival, as is often the case for migratory birds ([16]). On the other hand, they may incur in a catastrophe, for instance a spell of cold weather, that will kill a fraction of individuals that have arrived to their breeding grounds before the catastrophe. Clearly, the choice of focusing on arrival to the breeding grounds is purely exemplificative, and our model applies more generally to the timing of almost any life-history event. For example, it applies to timing of arrival to the wintering grounds, crossing of a geographical barrier like a mountain range, or to timing of reproduction, rather than arrival. From a biological point of view, the most interesting results we obtained can be summarized as follows. First, in presence of competition, a fraction of individuals arrive early during the season, in a period when they can incur in a catastrophe and therefore be killed. Interestingly, the stronger the competition, the earlier birds start arriving and may even arrive at the earliest time possible. Remarkably, there is a threshold value for the intensity of the competition above which a fraction of individuals arrive extremely early, i.e. at a time when they will certainly incur in the catastrophe. Hence, competition is able to force individuals to risk death if the payoff for an early arrival is sufficiently high. Second, a strong disturbance increases the fitness of individuals (fitness is equal for all individuals that follow the ESS) because, under a strong disturbance, the fraction of individuals arriving at a time when they can incur in the catastrophe decreases. Hence, a strong disturbance determines a later average arrival of the population. Actual distribution of arrival dates is therefore the balance between the contrasting pressures of competition and risk of death due to the catastrophe. Third, the ESS is not the strategy that determines the maximum average fitness of individuals in the population. Indeed,
a larger average fitness could be obtained if some individuals would accept a reduction in their own fitness for favouring other individuals. This result is not surprising since individuals are predicted to behave selfishly and adopt the strategy that maximizes their own fitness. We also tested our model under a climate change scenario, which is predicted to increase the frequency and strength of extreme meteorological events (22), like spells of unseasonal weather that can kill migratory birds. We obtained two further interesting results. Fourth, climate change, which is predicted to increase the strength of the disturbance, should determine an increase in the fitness when individuals are able to adapt their arrival times to the new ESS (second result above). However, the ESS implies a later average arrival of individuals (third result above). Differences among species or populations in the observed shifts in the timing of migration according to climate change may therefore be due to differences in the susceptibility of species or populations to extreme weather conditions, which in our model is accounted for by the strength of the disturbance. Since climate change is determining on the one side a general advancement of the timing of spring events (29 44), but on the other side it also increases the frequency of cold spells in spring (20), differences in the response of bird species or populations to climate change should be investigated also in respect to their susceptibility to unseasonable weather. Fifth, if the population is unable to adjust arrival times and continues following the previous timing, which is no more an ESS, the fitness of individuals declines (in many scenarios). It has been hypothesized that many migratory bird species, particularly long distance migrants, may be less able than short distance ones to advance their arrival to the breeding grounds because they are constrained by the timing of other life-history events (31). Consequently, they are forced to follow an arrival strategy that differs from the current ESS, and should suffer a reduction in fitness. Our model therefore gives an explanation of the possible mechanisms linking response to climate change and population trends and explaining why bird populations that did not show a response to climate change are declining (30). There is currently debate among biologists on whether the observed changes in arrival dates of migratory birds can be attributed more to micro-evolutionary processes or to phenotypic plasticity (14). If the response to climate change is due to phenotypic plastic response of individuals, then probably adaptation will be fast enough to keep the pace of climate change. In contrast, if timing of life history events is genetically controlled, a longer time may be needed for the new ESS to fix in the population, and in the meanwhile individual fitness will be reduced. In summary, the model we developed may contribute to our understanding of the processes determining the timing of life history events under the biologically realistic scenario of a catastrophe killing only a fraction of the individuals that incur in it. Our model explains how competition can induce a fraction of the population to arrive very early, despite facing a higher risk of death, as it is documented in several species (31). Moreover, our model also investigated the effect of climate change on the timing of life history events, and demonstrated that fitness should decline in a scenario of increased probability of catastrophe if the population is not able to adapt to the new climatic conditions.
5 Proofs

In this section one can find all the proofs of our results and some details about the remarks of the previous sections. We start with a lemma and its corollary.

**Lemma 5.1.** Let \( \{a_n\}_{n \geq 0}, \{b_n\}_{n \geq 0} \) and \( \{k_n\}_{n \geq 0} \) be such that \( a_n, b_n \geq 0 \) for all \( n \geq 0 \), \( b_n > 0 \) for some \( n \geq 0 \), \( k_{n+1} \geq k_n \) for all \( n \geq 0 \) and \( a_n = b_n k_n \) for all \( n \geq 0 \). Define \( n_0 := \min \{n \geq 0: b_n > 0\} \) and

\[
 f(t) := \begin{cases}
 \frac{\sum_{n \geq 0} a_n t^n}{\sum_{n \geq 0} b_n t^n} & t > 0 \\
 \frac{a_{n_0}}{b_{n_0}} & t = 0.
\end{cases}
\]

Then \( f \) is a nondecreasing function on \([0, +\infty)\). Moreover \( f \) is strictly increasing on \([0, +\infty)\) if and only if there exists \( m, n \) such that \( k_m > k_n \) and \( b_m, b_n > 0 \).

**Proof.** Note that \( f \) is continuous on \([0, +\infty)\) and differentiable on \((0, +\infty)\). We compute the derivative on \((0, +\infty)\) as

\[
f'(t) = \frac{\sum_{n \geq 1} na_n t^{n-1} \cdot \sum_{n \geq 0} b_n t^n - \sum_{n \geq 0} a_n t^n \cdot \sum_{n \geq 1} nb_n t^{n-1}}{\left(\sum_{n \geq 0} b_n t^n\right)^2} = \frac{\sum_{n \geq 0} \left[ \sum_{i=0}^n (i+1)(a_{i+1}b_{n-i} - a_i b_{i+1}) \right] t^n}{\left(\sum_{n \geq 0} b_n t^n\right)^2} = \frac{\sum_{n \geq 0} \left[ \sum_{i=0}^n (i+1)b_{i+1}b_{n-i}(k_{i+1} - k_{n-i}) \right] t^n}{\left(\sum_{n \geq 0} b_n t^n\right)^2}
\]

Now \((k_{n+1} - k_0)(n + 1)b_{n+1}b_0 \geq 0\) and, by using \( j = n - i - 1 \),

\[
\sum_{i=0}^{n-1} (i + 1)b_{i+1}b_{n-i}(k_{i+1} - k_{n-i})
\]

\[
= \frac{1}{2} \left[ \sum_{i=0}^{n-1} (i + 1)b_{i+1}b_{n-i}(k_{i+1} - k_{n-i}) + \sum_{j=0}^{n-1} (n-j)b_{n-j}b_{j+1}(k_{n-j} - k_{j+1}) \right]
\]

\[
= \frac{1}{2} \left[ \sum_{i=0}^{n-1} (i + 1)b_{i+1}b_{n-i}(k_{i+1} - k_{n-i}) - \sum_{j=0}^{n-1} (n-j)b_{j+1}b_{n-j}(k_{j+1} - k_{n-j}) \right]
\]

\[
= \frac{1}{2} \sum_{i=0}^{n-1} b_{i+1}b_{n-i}(k_{i+1} - k_{n-i})(i + 1 - (n-i)) = \frac{1}{2} \sum_{i=0}^{n-1} b_{i+1}b_{n-i}(k_{i+1} - k_{n-i})(2i + 1 - n).
\]

Since \((k_{i+1} - k_{n-i})(2i + 1 - n) \geq 0\) for all \( n, i \) such that \( n > i \geq 0 \) we have that \( f'(t) \geq 0 \) for all \( t \), hence \( f \) is non-decreasing.

20
Moreover, if \( k_m > k_n \) and \( b_m, b_n > 0 \) then \( m > n \) and \( \sum_{i=0}^{n+m-2} b_{i+1} b_{n-i} (k_{i+1} - k_{n-i})(2i+1-n) \geq b_m b_n (k_m - k_n)(m-n) > 0 \) (just take \( i = m-1 \)). This implies \( f'(t) > 0 \) for all \( t \in (0, +\infty) \), whence \( f \) is strictly increasing on \([0, +\infty)\). On the other hand if \( k_n = k_m \) for all \( n, m \) such that \( b_n b_m > 0 \), clearly \( f(t) = k_0 \) for all \( t \in [0, +\infty) \).

\[\square\]

**Corollary 5.2.** Suppose that \( \bar{a} > a > 0 \) and \( p \leq 1 \). The the function \( f(t) := (e^{\bar{a}t} - p)/(e^{at} - p) \) is strictly increasing in \([0, +\infty)\).

**Proof.** Apply Lemma 5.1 using \( a_0 = b_0 = 1 - p, a_n = \bar{a}^n / n! \) for all \( n \geq 1, b_n = a^n / n! \) for all \( n \geq 1 \) and \( k_n = (\bar{a}/a)^n \).

\[\square\]

The following is a brief remark which proves some of the properties of the functions \( \gamma \) and \( \lambda \) (the others are straightforward).

**Details on Remark 3.4.** Most of the results about the functions \( a_M, \gamma, \lambda \) and \( x_c \) follow easily by checking the monotonicity and the the continuity (in each variable separately) of the l.h.s. and r.h.s. of the defining equations. We highlight just the main details.

1. Since the l.h.s. of equation (3.2) is strictly decreasing, continuous with respect to \( p \) and strictly increasing, continuous with respect to \( a_M \) and since the r.h.s. is strictly decreasing, continuous with respect to \( p \) we have that \( p \mapsto a_M(p) \) is strictly decreasing and continuous. As for the limit we note that, for every fixed \( \beta \in (0, +\infty) \),

\[
p \int_1^{\exp(\beta)} \frac{dz}{z^{1-p} - p} \to \begin{cases} 0 & \text{if } p \to 0^+ \\ +\infty & \text{if } p \to 1^- \end{cases}
\]

since \( 1/(z^{1-p} - p) \downarrow 1/z \) pointwise in the first case and the Bounded Convergence Theorem applies, while \( 1/(z^{1-p} - p) \uparrow +\infty \) pointwise in the second case and the Monotone Convergence Theorem applies. The limits follow easily by standard arguments.

2. Since the r.h.s. of equation (3.3) is strictly increasing and continuous with respect to \( p \) and with respect to \( a \) and since the l.h.s. is continuous and nonincreasing with respect to \( x_c \) we have that the maps \( a \mapsto x_c \) and \( p \mapsto x_c \) are strictly increasing. As for the continuity, note that, by definition, for every \( \beta > x_c(a_0, p_0, f) \) we have \( \int_\beta^{\gamma_f} f(x)dx < \int_{x_c(a_0, p_0, f)}^{\gamma_f} f(x)dx \) hence

\[
\lim_{a \to a_0^+} \left( \int_\beta^{\gamma_f} f(x)dx - \left(1 - p_0 + \left( \int_{1}^{\exp(a)} \frac{dz}{z^{1-p_0} - p_0} \right)^{-1} \right)^{-1} \right) < 0
\]

\[
\lim_{p \to p_0^-} \left( \int_\beta^{\gamma_f} f(x)dx - \left(1 - p + \left( \int_{1}^{\exp(a_0)} \frac{dz}{z^{1-p} - p} \right)^{-1} \right)^{-1} \right) < 0.
\]

These inequalities imply that, eventually, the maximal solution \( x_c(a, p_0, f) \in (x_c(a_0, p_0, f), \beta) \) (resp. \( x_c(a_0, p, f) \in (x_c(a_0, p_0, f), \beta) \)). The limits from the right can be treated analogously by carefully dealing with the intervals where \( \beta \mapsto \int_\beta^{\gamma_f} f(x)dx \) is constant.
Let us prove the limits in equation (3.5). By using the monotonicity of \( p \mapsto x_c \), we have that
\[
x_c(a,p,f) \leq x_c(a,0,f).
\]
Since the r.h.s. of equation (3.3) equals \( a/(1+a) < 1 \) when \( p = 0 \) we get that \( x_c(a,0,f) < f \). In order to compute the second limit we observe that the r.h.s. of
equation (3.3) tends to 0 as \( a \to 0^+ \). As for the second line in equation (3.5), note that for every \( \beta > f \) we have that \( \int_\beta^f f(x)dx < 1 \) hence \( \int_\beta^f f(x)dx - \left(1 - p + \left(\int_1^{exp(a)} \frac{dz}{z^{p-1}}\right)^{-1}\right)^{-1} \rightarrow \int_\beta^f f(x)dx - 1 < 0 \) eventually as \( p \to p_M(a)^- \).

3. The continuity follows from the continuity of the r.h.s. of equation (3.4) with respect to \( p \), from the continuity of the l.h.s. with respect to \( p, a \) and \( \gamma \) and from the monotonicity with respect to \( \gamma \).

Let us prove that \( \lim_{a \to \infty} \gamma(a,p) = p \). We define \( G(a,p,\gamma) := \exp(-a\gamma) \int_{\exp(a)}^{\exp(a)} \frac{dv}{v^{\gamma-p}} \) and we can assume \( p \in (0,1) \). Clearly, \( \int_{\exp(a)}^{\exp(a)} \frac{dv}{v^{\gamma-p}} \sim \int_{\exp(a)}^{\exp(a)} \frac{dv}{v^p} = (\exp(ap) - \exp(a\gamma p))/p \) as \( a \to +\infty \). Hence for every fixed \( \gamma \) and \( p \) and for every \( \varepsilon > 0 \) we have
\[
(1 + \varepsilon)(\exp(a(p-\gamma)) - \exp(a\gamma(p-1)))/p > G(a,p,\gamma) > (\exp(a(p-\gamma)) - \exp(a\gamma(p-1)))/p
\]
eventually as \( a \to +\infty \). Hence
\[
\lim_{a \to +\infty} G(a,p,\gamma) = \begin{cases} 
+\infty & \text{if } \gamma < p \\
0 & \text{if } \gamma > p
\end{cases}
\]
thus for every \( \bar{\gamma}, \tilde{\gamma} \) satisfying \( \bar{\gamma} < p < \tilde{\gamma} \), eventually as \( a \to +\infty \), the solution \( \gamma(a,p) \) to equation (3.4), that is \( G(a,p,\gamma) - 1/p = 0 \), satisfies \( \gamma(a,p) \in (\bar{\gamma}, \tilde{\gamma}) \). This implies \( \lim_{a \to \infty} \gamma(a,p) = p \).

In order to prove that \( \gamma(a,p) < p \) for all \( a \geq 0 \), \( p \in (0,1) \), it is enough to show that \( G(a,p,\gamma) < 1/p \) for all \( a \geq 0 \), \( p \in (0,1) \). Indeed, in that case, the solution \( \gamma(a,p) \) of \( G(a,p,\gamma) - 1/p = 0 \) satisfies \( \gamma(a,p) \in (0,p) \) (note that \( \gamma \mapsto G(a,p,\gamma) \) is strictly decreasing for all \( a > 0 \)). Observe that
\[
G(a,p,\gamma) = \frac{\exp(a(p-\gamma)) - \exp(-a\gamma(1-p))}{p} - \exp(-a\gamma) \int_{\exp(a)}^{\exp(a)} \frac{1}{v^{1-p} - p - 1/v^{1-p}} dv
\]
\[
< \frac{\exp(a(p-\gamma)) - \exp(-a\gamma(1-p))}{p} - \exp(-a\gamma) \int_{\exp(a)}^{\exp(a)} \frac{p}{v^{2(1-p)}} dv
\]
\[
= \frac{\exp(a(p-\gamma)) - \exp(-a\gamma(1-p))}{p} - \Delta(a,p,\gamma)
\]
where
\[
\Delta(a,p,\gamma) := \begin{cases} 
e^{-a\gamma} a(1-\gamma)/2 & \text{if } p = 1/2 \\
e^{-a\gamma} 2p^{-1}(e^{a(2p-1)} - e^{a\gamma(2p-1)}) & \text{if } p \neq 1/2.
\end{cases}
\]
When \( \gamma = p \) we have \( G(a,p,p) = 1/p - (e^{-ap(1-p)}/p - \Delta(a,p,p)) \), hence it is enough to prove that \( e^{-ap(1-p)}/p - \Delta(a,p,p) > 0 \), that is, \( F_p(a) := pe^{ap(1-p)}\Delta(a,p,p) < 1 \). The first case
is $\gamma = p = 1/2$; thus, $F_p(a) = e^{-a/4}a/8$ which attains its maximum value (in $[0, +\infty)$) at $a = 4$ and $F_p(2) = e^{-1/2} < 1$. The second case is $\gamma = p \neq 1/2$ where $F_p(a) = p^2(e^{-a(1-p)^2} - e^{-ap(1-p)})/(2p-1)$. Note that $F_p(0) = 0$, $F_p(a) > 0$ for all $a > 0$ and $F_p(a) \to 0$ as $a \to +\infty$. Hence $F_p$ admits a global maximum in $[0, +\infty)$, which must be a stationary point since $F_p$ is differentiable. By taking the derivative $F'_p(a) = p^2(p(1-p)e^{-ap(1-p)} - (1-p)^2e^{-a(1-p)^2})/(2p-1)$ we have that a stationary point $\bar{a}$ must satisfy $e^{-ap(1-p)} - (1-p)e^{-a(1-p)^2}/p = 0$. Hence $F_p(\bar{a}) = pe^{-\bar{a}(1-p)^2} < 1$. This proves that $\gamma(a, p) < p$ for all $p \in (0, 1)$ and $a > 0$.

Now we prove that $a \mapsto \gamma(a, p)$ is strictly increasing in $[a_M(p), +\infty)$ for all $p \in (0, 1)$. Since $\gamma \mapsto G(a, p, \gamma)$ is strictly decreasing for every fixed $a > 0$, it is enough to prove that $a \mapsto G(a, p, \gamma)$ is strictly increasing (for fixed $\gamma \leq p < 1$) to obtain that $a \mapsto \gamma(a, p)$ is strictly increasing where it is defined by equation (3.4) (by standard arguments for implicitly defined functions). By continuity it is enough to prove that $G(\bar{a}, p, \gamma) > G(a, p, \gamma)$ where $\bar{a} > a > 0$ (the case $a = 0$ would follow easily).

To this aim, let us replace the variable in the integral defining $G$ in the following way: $z = \alpha v + \beta$ where $\alpha = (e^{\bar{a}} - e^{\bar{a}p})/(e^{\bar{a}} - e^{\alpha})$ and $\beta = -(e^{\bar{a}+\alpha} - e^{\bar{a}+\alpha p})/(e^{\bar{a}} - e^{\alpha})$ (note that $\beta < 0$ since $\gamma < 1$). This implies that when $v = e^{\alpha}$ then $z = e^{\alpha} \gamma$ and when $v = e^{\bar{a}}$ then $z = e^{\bar{a}}$. Whence

$$G(a, p, \gamma) = e^{-\bar{a} \gamma}e^{\gamma(\bar{a} - a)} \int_{e^{\bar{a} \gamma}}^{e^{a \gamma}} \frac{dz}{z^{1-p} - p} = e^{-\bar{a} \gamma} \int_{e^{\bar{a} \gamma}}^{e^{a \gamma}} \frac{1}{z^{1-p} - p} \left( \frac{z^{1-p} - p}{\left(\frac{z - \beta}{\alpha}\right)^{1-p} - p} \cdot \frac{e^{\gamma(\bar{a} - a)}}{\alpha} \right) dz = (*) .$$

Observe that $(e^{\gamma(\bar{a} - a)})/\alpha = (e^{(1-\alpha)} - 1)/(e^{(1-\alpha)} - 1)$. Moreover

$$\frac{z^{1-p} - p}{\left(\frac{z - \beta}{\alpha}\right)^{1-p} - p} = \alpha^{1-p}(\frac{z}{\alpha})^{1-p} - p/\alpha^{1-p} = \alpha^{1-p} \left( 1 - \left(\frac{z + |\beta|}{\alpha}\right)^{1-p} - \left(\frac{z}{\alpha}\right)^{1-p} - p(1 - 1/\alpha^{1-p}) \right)$$

which is strictly increasing with respect to $z$ since $z/\alpha < (z + |\beta|)/\alpha$. Hence $(z + |\beta|)/\alpha^{1-p} - (z/\alpha)^{1-p}$ is nonincreasing (since $1 - p \leq 1$) and $(z + |\beta|)/\alpha^{1-p} - p$ is strictly increasing. This implies that, for all $z \in [e^{\alpha}, e^\bar{a})$,

$$\frac{z^{1-p} - p}{\left(\frac{z - \beta}{\alpha}\right)^{1-p} - p} \cdot \frac{\gamma(\bar{a} - a)}{\alpha} < \frac{e^{\bar{a}(1-p)} - p}{e^{\alpha(1-p)} - p} \cdot \frac{e^{\alpha(1-\gamma)} - 1}{e^{\alpha(1-\gamma)} - 1} \leq \frac{e^{\bar{a}(1-p)} - 1}{e^{\alpha(1-p)} - 1} \cdot \frac{e^{\alpha(1-\gamma)} - 1}{e^{\alpha(1-\gamma)} - 1}$$

$$\leq \frac{e^{\bar{a}(1-p)} - 1}{e^{\alpha(1-p)} - 1} \cdot \frac{e^{\alpha(1-p)} - 1}{e^{\alpha(1-p)} - 1} = 1$$

where in the second inequality we used $(x - p)/(y - p) \leq (x - 1)/(y - 1)$ for all $x \geq y > 1 \geq p$, while in the last inequality we applied Corollary 5.2 (since $\gamma \leq p$). Finally, this yields

$$(*) < e^{-\bar{a} \gamma} \int_{e^{\bar{a} \gamma}}^{e^{a \gamma}} \frac{dz}{z^{1-p} - p} = G(\bar{a}, p, \gamma).$$
Remark 5.3. The continuity of the function $\lambda(a, p)$ is easy. In the interval $[0, a_M(p)]$ the function $a \mapsto \lambda(a, p)$ is strictly decreasing since the integral in the r.h.s. of equation (3.7) is strictly increasing for all $p \in (0, 1)$. If $a \in (a_M(p), +\infty)$ then, using equation (3.4), we have that $\lambda(a, p)$ is a solution to

$$
\lambda \int_{p/\lambda}^{\exp(a)} \frac{dz}{z^{1-p} - p} = 1
$$

and, since the l.h.s. of this equation is strictly increasing with respect to $a$ and $\lambda$, standard arguments imply that $a \mapsto \lambda(a, p)$ is strictly decreasing.

We show now that $p \mapsto \lambda(a, p)$ is strictly decreasing. Let us consider now the second expression for $\lambda$, namely $p \exp(-a\gamma)$, which holds for $p > p_M(a)$ where we recall that $p_M(a)$ is the unique solution for $\int_1^{\exp(a)} \frac{dz}{z^{1-p} - p} = \frac{1}{p}$ with respect to $p$. From equation (3.4) we have that, for every fixed $a > 0$, the function $p \mapsto y(p) := p \exp(-a\gamma(a, p))$ is implicitly defined by the equation $F_a(y, p) = 0$ where

$$
F_a(y, p) = y \int_{p/y}^{\exp(a)} \frac{dv}{v^{1-p} - p} - 1.
$$

The solution to the previous equation is uniquely defined in $(p_M, p)$ since $y \mapsto F_a(y, p)$ is strictly increasing for every fixed $p \in (0, 1)$ and $F_a(p_M, p) < p_M/p_M - 1 = 0$, $F_a(p, p) = p/p_M - 1 > 0$. We can compute, using similar arguments as before,

$$
\partial_p F_a(y, p) = -\frac{1}{(p/y)^{1-p} - p} + y \int_{p/y}^{\exp(a)} \frac{v^{1-p} \ln(v) + 1}{(v^{1-p} - p)^2} dv
$$

$$
> -\frac{1}{(p/y)^{1-p} - p} + \frac{1}{1-p} y \int_{p/y}^{\exp(a)} \frac{dv}{v^{1-p} - p}
$$

$$
= -\frac{1}{(p/y)^{1-p} - p} + \frac{1}{1-p} > 0
$$

for every $y > 0$ since the integrand is strictly positive for every $z > 1$; indeed the function $x \mapsto x \ln(x) + 1 - x = x(\ln(x) - 1) + 1$ is differentiable in $(1, +\infty)$ and continuous in $[1, +\infty)$ and the derivative is $\ln(x) > 0$ for all $x > 1$. This implies that $p \mapsto \lambda(a, p)$ is strictly decreasing for every fixed $a > 0$.
where in the last equality we used the fact that, since $F_a(y,p) = 0$, then $\int_p^y \frac{\exp(a)}{v^{1-p}} dv = 1$. The last inequality holds since $p > y$. By standard arguments, $\partial_p F_a(y,p) > 0$ implies that $p \mapsto \lambda(a, p)$ is strictly decreasing for every $a > 0$.

Before proving Theorem 3.5, we prove that an ESS is of the form $\mu = \gamma \delta_0 + (1 - \gamma) \nu$, where $\nu$ is an absolutely continuous probability measure.

**Lemma 5.4.** Let $\mu$ be an ESS and fix $p \in [0, 1)$. Then for some $\gamma \in [0, 1]$, $\mu = \gamma \delta_0 + (1 - \gamma) \nu$, where $\nu$ is an absolutely continuous probability measure. Moreover if $\min \supp(\mu) \subseteq \supp(\mu) \supseteq [\min \supp(\mu), \bar{t}_f] \cap \supp(\phi)$ and if $\min \supp(\mu) < \min \supp(\nu)$ then $\supp(\nu) \supseteq \supp(\phi)$. Finally, $\phi_\mu$ is constant on $[\min \supp(\mu), +\infty)$ and equals $\lambda$.

**Proof.** We already noted that we can write equivalently

$$
\phi_\mu(x) = \exp(-a F_\mu(x)) \left[ \int_0^x \exp(a(1-p)F_\mu(z)) f(z)dz + p \int_x^{+\infty} f(z)dz \right]
$$

since $\supp(\phi) \subseteq [0, \bar{t}_f]$. From this equation we can see easily that $\phi$ is right-continuous on $[0, +\infty)$; moreover it is left-continuous at $x$ if and only if $\mu(\{x\}) = 0$. If $(\alpha, \beta)$ is such that $\mu((\alpha, \beta]) = 0$ then $(\alpha, \beta] \cap \supp(\phi) \neq \emptyset$, if and only if $\phi(\beta) > \phi(\alpha)$. Indeed,

$$
\phi_\mu(\beta) - \phi_\mu(\alpha) = \exp(-a F_\mu(\alpha)) \left( \exp(a(1-p)F_\mu(\alpha) - p) \int_{\alpha}^{\beta} f(z)dz \right) > 0.
$$

(5.11)

As a consequence, if $\mu((\alpha, \beta]) = 0$ then $(\alpha, \beta) \cap \supp(\phi) \neq \emptyset$ if and only if $\lim_{t \to \beta^-} \phi_\mu(t) > \phi_\mu(\alpha)$. Moreover if $\{x_n\}_{n \in \mathbb{N}}$ is such that $x_n \in \supp(\mu)$, $x_n \neq x$ for all $n \in \mathbb{N}$ and $x_n \uparrow x$ then $x \in \supp(\mu)$ and $\mu(\{x\}) = 0$. The first assertion, namely $x \in \supp(\mu)$, comes from the fact that the support of a measure is a closed set. Suppose, by contradiction, that $x$ is an atom; clearly $\phi(x_n) = \lambda$ for all $n$, since $\mu$ is an ESS, and $\lim_{t \to x^-} \phi_\mu(t) > \phi_\mu(x)$ hence $\phi_\mu(x) < \lambda$ which is a contradiction. This proves that the only atom, if any, of $\mu$ must be 0. Thus $\mu = \gamma \delta_0 + (1 - \gamma) \nu$, where $\gamma = \mu(0)$ and $\nu$ is nonatomic.

We prove now that if $\alpha < \beta$, $\alpha \in \supp(\mu)$ and $\beta \in \supp(\phi)$, then $\beta \in \supp(\mu)$; this implies $\supp(\mu) \supseteq [\min \supp(\mu), \bar{t}_f] \cap \supp(\phi)$. By contradiction if $\beta \not\in \supp(\mu)$ there exists $\varepsilon > 0$ such that $(\beta - \varepsilon, \beta + \varepsilon) \cap \supp(\mu) = \emptyset$. Let $\tilde{\beta} := \max(\supp(\mu) \cap [0, \beta])$ then $\tilde{\beta} < \beta$. Since $\beta \in \supp(\phi)$, $\int_{\beta - \varepsilon}^{\beta + \varepsilon} f(x)dx > 0$. Clearly $(\tilde{\beta}, \beta + \varepsilon) \cap \supp(\mu) = \emptyset$, as a consequence of equation (5.11), $0 < \lim_{t \to (\beta + \varepsilon)^-} \phi_\mu(t) - \phi_\mu(\tilde{\beta}) = \lim_{t \to (\beta + \varepsilon)^-} \phi_\mu(t) - \lambda$. Hence there exists $t \in (\beta - \varepsilon, \beta + \varepsilon)$ such that $\phi_\mu(t) > \lambda$ but this contradicts the definition of ESS.

Let us prove that $[\min \supp(\mu), \bar{t}_f] \supseteq \supp(\mu)$. Observe that, for every $\beta > \bar{t}_f$ we have

$$
\phi_\mu(\beta) - \phi_\mu(\bar{t}_f) = \left( \exp(-a F_\mu(\beta)) - \exp(-a F_\mu(\bar{t}_f)) \right) \int_0^{\bar{t}_f} \exp(a(1-p)F_\mu(z)) f(z)dz \leq 0.
$$
On the other hand, if $\beta \in \text{supp}(\mu)$, there exists $\varepsilon \geq 0$ such that $F_\mu(\beta + \varepsilon) > F_\mu(\bar{t}_f)$ and $\beta + \varepsilon \in \text{supp}(\mu)$. This implies $\phi_\mu(\beta + \varepsilon) < \phi_\mu(\bar{t}_f)$ which contradicts the definition of an ESS. Thus $[\min \text{supp}(\mu), \bar{t}_f] \supseteq \text{supp}(\mu)$.

If $\min \text{supp}(\mu) < \min \text{supp}(\nu)$ then $\gamma > 0$ and $0 = \min \text{supp}(\mu) < \min \text{supp}(\nu)$. On the other hand, $\text{supp}(\nu) \supseteq \text{supp}(\mu) \supseteq \text{supp}(\nu) \cup \{0\}$, that is, $\text{supp}(\mu) \setminus \{0\} = \text{supp}(\nu) \setminus \{0\}$. Since when $\min \text{supp}(\mu) = 0$ we have $\text{supp}(\mu) \supseteq \text{Esupp}(f)$, then $\text{supp}(\nu) \setminus \{0\} \supseteq \text{Esupp}(f) \setminus \{0\}$ which implies $\text{supp}(\nu) = \text{supp}(\nu) \setminus \{0\} \supseteq \text{Esupp}(f) \setminus \{0\} = \text{Esupp}(f)$.

We are left to prove that $\nu$ is absolutely continuous. First of all we note that, from equation (2.1),

$$\phi_\mu(x) = \exp(-aF_\mu(x))H_\mu(x)$$

where $H_\mu(x) = \int_0^x \exp(a(1-p)F_\mu(z))f(z)dz + p\int_x^{+\infty} f(z)dz$

is absolutely continuous and nondecreasing on $[0, \bar{t}_f]$. Since the only atom of $\mu$, if any, is $0$ and $\phi_\mu$ is right-continuous, clearly $\phi_\mu$ is continuous on $[0, \bar{t}_f]$. It is well-known that any open set in $\mathbb{R}$ can be decomposed into a disjoint, at most countable union of open intervals, hence $(0, +\infty) = (\text{supp}(\mu) \setminus \{0\}) \cup \bigcup_{j \in J} I_j$ where $\{I_j\}_{j \in J}$ is an at most countable disjoint union of open intervals in $(0, +\infty)$. By definition, $\phi_\mu(x) = \lambda$ for all $x \in \text{supp}(\mu)$. Since $\text{supp}(\mu) \supseteq (\min \text{supp}(\mu) \cap \text{Esupp}(f), \bar{t}_f)$ then $\int_{I_j} f(x)dx = 0$ for all $I_j \subseteq (\min \text{supp}(\mu), +\infty)$. As a consequence of equation (5.11), $\phi_\mu$ is constant on such intervals $I_j$, but, since the value of $\phi_\mu$ at the extremal points of $I_j$ is $\lambda$, then $\phi_\mu(x) = \lambda$ for all $x \in I_j$. This proves that $\phi_\mu(x) = \lambda$ for all $x \geq \min \text{supp}(\mu)$. Hence $\lambda = \exp(-aF_\mu(x))H_\mu(x)$ for all $x \geq \min \text{supp}(\mu)$ which implies

$$F_\mu(x) = \begin{cases} \frac{1}{a} \log \left( \frac{H_\mu(x)}{\lambda} \right) & \text{if } x \geq \min \text{supp}(\mu) \\ 0 & \text{if } x < \min \text{supp}(\mu). \end{cases}$$

(5.12)

By composition, $F_\mu$ is absolutely continuous on $(\min \text{supp}(\mu), \bar{t}_f)$. Hence $F_\nu$ is absolutely continuous on $(\min \text{supp}(\mu), \bar{t}_f)$ (since $F_\mu(x) - (1-\gamma)F_\nu(x) = \gamma$ for all $x \geq 0$) and this implies that $\nu$ is an absolutely continuous measure (since $\text{supp}(\nu) \subseteq [\min \text{supp}(\mu), \bar{t}_f]$).

Given a measurable subset $I \subseteq \mathbb{R}$, we denote by $L^1(I)$ the set of real, measurable functions on $I$ which are integrable with respect to the Lebesgue measure. When a different measure $\rho$ needs to be specified, we write $L^1(I, \rho)$ instead.

**Remark 5.5.** A well-known characterization which will be used in the sequel is the following Lebesgue’s fundamental theorem of calculus (see for instance [38, Theorem 7.18]). A function $G$ is absolutely continuous on a compact interval $I$ if and only if there exists a function $g \in L^1(I)$ such that for some ($\iff$ for all) $\alpha \in I$ and for all $\beta \in I$, $G(\beta) - G(\alpha) = \int_\alpha^\beta g(x)dx$; in that case, for almost every $x \in I$, $G$ is differentiable at $x$ and $G'(x) = g(x)$.
This implies that an absolutely continuous function $G$ on $I$ is constant if and only if $G'(x) = 0$ for almost every $x \in I$.

Moreover consider two functions $h : I \to J$, $k : J \to Y$; if $k$ is absolutely continuous and $h$ is monotone and absolutely continuous then $k \circ h$ is absolutely continuous. Similarly, if $k$ is a Lipschitz function and $h$ is absolutely continuous then $k \circ h$ is absolutely continuous. If $h_1 : I \to \mathbb{R}$ is absolutely continuous then $h + h_1$ is absolutely continuous and the same holds for $h \cdot h_1$ if $I$ is compact.

Finally if $k$ is differentiable everywhere and $h$ is differentiable almost everywhere clearly we have $(k \circ h)'(x) = k'(h(x)) \cdot h'(x)$ almost everywhere and, if in addition $k \circ h$ is absolutely continuous,

$$k \circ h(x) - k \circ h(x_0) = \int_{x_0}^{x} (k \circ h)'(z)dz = \int_{x_0}^{x} k'(h(z)) \cdot h'(z)dz = (*) \quad (5.13)$$

for all $x_0, x \in I$. If, in addition, $h$ is absolutely continuous then

$$\int_{h(x_0)}^{h(x)} k'(y)dy = k \circ h(x) - k \circ h(x_0) = (*). \quad (5.14)$$

A function $k$ is locally Lipschitz on $I$ if and only if for every $x_0 \in I$ there exists $\delta > 0$ and $M > 0$ such that $|x - x_0| < \delta$, $|\bar{x} - x_0| < \delta$ implies $|h(x) - h(\bar{x})| \leq M|x - \bar{x}|$. By elementary analysis, if $h$ is a locally Lipschitz function on $I$ and $I' \subseteq I$ is compact then there exists $M > 0$ such that for all $x, \bar{x} \in I'$ we have $|h(x) - h(\bar{x})| \leq M|x - \bar{x}|$ (that is, $h$ is globally Lipschitz on every compact subset of $I$). It is easy to show that a locally Lipschitz function on $I$ is absolutely continuous on $I$ (one can prove it on every compact subset and then use the fact that $I$ is the union of an increasing family of compact subintervals). Hence the following result holds.

Given an interval $I$, if $k$ is locally Lipschitz on $I$, differentiable everywhere and $h$ is absolutely continuous on $I$ then the equalities $(5.13)$ and $(5.14)$ hold; moreover $k \circ h$ is constant on $I$ if and only if $(k' \circ h)(x) \cdot h'(x) = 0$ almost everywhere in $I$.

Proof of Theorem 3.5 By Lemma 5.4 we know that an ESS can be written as $\mu = \gamma \delta_0 + (1 - \gamma)\nu$, where $\nu$ is an absolutely continuous measure and $\text{supp}(\mu) \supseteq [x_\mu, \bar{c}] \cap \text{Esupp}(f)$, where $x_\mu := \text{min supp}(\mu)$ (we will show later that $x_\mu = x_c$). Since $F_\mu(y) - (1 - \gamma)F_\nu(y) = \gamma$ for all $y \geq 0$, we have that $F_\mu$ is absolutely continuous on $[0, +\infty)$.

Since $\phi_\mu$ is absolutely continuous, we can take the derivative of $\phi_\mu$ in (2.1), for almost every $y > 0$,

$$\phi'_\mu(y) = -a(1 - \gamma)g(y)\phi_\mu(y) + \exp(-aF_\mu(y)) \left[ \exp(a(1 - p)F_\mu(y)) - p \right] f(y), \quad (5.15)$$

where $g$ is the derivative of $\nu$. From now on it will be tacitly understood that the derivatives and equalities involving them, are defined and hold almost everywhere. From Lemma 5.4 we know that for all $y > x_\mu$ we have $\phi_\mu(y) = \lambda$ hence $\phi'_\mu(y) = 0$. Thus

$$g(y) = \frac{f(y)}{a(1 - \gamma)\lambda} \exp(-aF_\mu(y)) \left[ \exp(a(1 - p)F_\mu(y)) - p \right].$$
Let \( z := \exp(aF_\mu) \). Using the last result of Remark 5.5 (by taking \( I = [0, +\infty) \), \( k(x) := \exp(ax) \) and \( h := F_\mu \)), the previous equation is equivalent to

\[
z'(y) = \frac{f(y)}{\lambda} (z(y)^{1-p} - p),
\]

which, since \( z(y)^{1-p} > p \) for all \( y \geq 0 \), is in turn equivalent to

\[
\frac{z'(y)}{z(y)^{1-p} - p} = \frac{f(y)}{\lambda},
\]

with the condition \( z(x_\mu) = \exp(a\gamma) \). By Remark 5.5, this is equivalent to

\[
\int_{\exp(a(1-\gamma)F_\nu(x) + a\gamma)}^{\exp(a(1-\gamma)F_\nu(x+\varepsilon) + a\gamma)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} \int_{x_\mu}^{x} f(y)dy,
\]

which, once we prove that \( x_c = x_\mu \), is equivalent to equation (3.6). This proves that given \( \gamma \), \( F_\nu \) is uniquely defined by the previous equation. From the previous equation, for all \( x \in [x_\mu, \bar{t}_f] \),

\[
\int_{\exp(a(1-\gamma)F_\nu(x-\varepsilon) + a\gamma)}^{\exp(a(1-\gamma)F_\nu(x) + a\gamma)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} \int_{x-\varepsilon}^{x+\varepsilon} f(y)dy,
\]

which implies that \( \text{supp}(\nu) = [x_\mu, \bar{t}_f] \cap \text{Esupp}(f) \). Now, since \( \text{supp}(\mu) \setminus \{0\} = \text{supp}(\nu) \setminus \{0\} \), from Lemma 5.4 we have that either \( \mu = \nu \) (hence \( \text{supp}(\mu) = [x_\mu, \bar{t}_f] \cap \text{Esupp}(f) \) and \( \min\text{supp}(\mu) = \min\text{supp}(\nu) \)) or \( \gamma > 0 \) and \( x_\mu = 0 \). In this case \( \text{supp}(\nu) = \text{Esupp}(f) \) and \( \text{supp}(\mu) = \text{Esupp}(f) \cup \{0\} \).

In particular, since \( x_\mu \in \text{supp}(\mu) \), when \( \mu = \nu \) (that is, \( \gamma = 0 \)) we have that \( x_\mu \in \text{Esupp}(f) \). Clearly the measure \( \nu \) is supported in \([0, \bar{t}_f] \), but it is a probability measure if and only if \( F_\nu(\bar{t}_f) = 1 \), therefore, by using equation (5.16), \( x_\mu \) and \( \gamma \) must satisfy

\[
\int_{\exp(a(1-\gamma)F_\nu(x-\varepsilon) + a\gamma)}^{\exp(a(1-\gamma)F_\nu(x) + a\gamma)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} \int_{x_\mu}^{\bar{t}_f} f(y)dy.
\]

We note that \( \lambda = \phi_\mu(\min\text{supp}(\mu)) = \phi_\mu(x_\mu) \). If \( \gamma = 0 \) then \( \mu = \nu \) hence, from equation (5.12), by continuity of \( F_\mu \) at \( x = \min\text{supp}(\mu) \equiv x_\mu \) we have \( \lambda = H_\mu(x_\mu) \), that is

\[
\lambda = \int_0^{x_\mu} f(y)dy + \int_{x_\mu}^{\bar{t}_f} f(y)dy = 1 - (1-p) \int_{x_\mu}^{\bar{t}_f} f(y)dy
\]

since \( \exp(a(1-p)F_\mu(y)) = 1 \) for all \( y \in [0, x_\mu] \).

If \( \gamma > 0 \) then \( x_\mu = 0 \) and, from equation (2.1), \( \lambda = \phi_\mu(0) = p \exp(-a\gamma) \) which is the second line of equation (5.1).

Let \( a \leq a_M \). If \( \gamma > 0 \) then by equation (5.17) and the discussion thereafter,

\[
\frac{1}{p} = \int_1^{\exp(aM)} \frac{dz}{z^{1-p} - p} \geq \int_1^{\exp(a)} \frac{dz}{z^{1-p} - p} > \int_{\exp(a)}^{\exp(\gamma)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} > \frac{1}{p},
\]

28
which is a contradiction. If $\gamma = 0$ then by plugging the explicit value of $\lambda = 1 - (1 - p) \int_{x_\mu}^{t_f} f(y)dy$ into (5.17), we get (3.3) (with $x_\mu$ instead of $x_c$) and since we showed that $x_\mu \in E\text{Supp}(f)$, thus it must be the (unique) maximal solution to equation (3.3), that is $x_\mu = x_c$. This proves that $a \leq a_M$ implies $\gamma = 0$ and $x_c \geq t_f$. Since the r.h.s. of equation (3.3) is strictly less than 1 (resp. equal to 1) when $a < a_M$ (resp. $a = a_M$) then equation (3.3) yields $x_c > t_f$ (resp. $x_c = t_f$). In order to obtain the first line of equation (3.7) just consider the expression of $\int_{x_c}^{t_f} f(y)dy$ given by the r.h.s. of equation (3.3) and plug it in equation (5.18) (recalling that $x_\mu = x_c$).

Let $a > a_M$. If $\gamma = 0$ then, by the definition of $a_M$, equation (5.17) and the discussion thereafter,

$$\frac{1}{\lambda} \int_{x_\mu}^{t_f} f(y)dy = \frac{\int_{x_\mu}^{t_f} f(y)dy}{1 - (1 - p) \int_{x_\mu}^{t_f} f(y)dy} \leq \frac{1}{p} = \int_1^{\exp(a_M)} \frac{dz}{z^{1-p} - p}$$

$$< \int_1^{\exp(a)} \frac{dz}{z^{1-p} - p} = \frac{1}{\lambda} \int_{x_\mu}^{t_f} f(y)dy,$$

which is a contradiction. If $\gamma > 0$ then $x_\mu = 0$ (which coincides with the definition of $x_c$ given before equation (3.3)) and by plugging the explicit value of $\lambda = p \exp(-a \gamma)$ in equation (5.17) we have

$$\frac{1}{p} = \exp(-a \gamma) \int_{\exp(a \gamma)}^{\exp(a \gamma)} \frac{dz}{z^{1-p} - p} = \int_{1}^{\exp(a(1-\gamma))} \frac{dz}{(z \exp(a \gamma))^{1-p} - p},$$

which has a unique solution $\gamma$. Note that the r.h.s. of the equation is a decreasing continuous function of $\gamma$, say $K(\gamma)$; moreover $K(0) > 1/p$ by (3.2) and

$$K(1 - a_M/a) = \int_{1}^{\exp(a_M)} \frac{dz}{(z \exp(a - a_M))^{1-p} - p} < \int_{1}^{\exp(a_M)} \frac{dz}{z^{1-p} - p} = \frac{1}{p}.$$ 

This implies that the unique solution $\gamma \in (0, 1 - a_M/a)$; $\gamma < p$ was proved in Remark 5.3.

Before giving the details on Remark 3.6 we need a Lemma and another remark.

**Lemma 5.6.** Let $\mu$ and $\nu$ be two finite measures on $\mathbb{R}$. Then the following conditions are equivalent:

1. $\int h(x)\mu(dx) \geq \int h(x)\nu(dx)$ for every nondecreasing, measurable $h \in L^1(\mathbb{R}, \mu) \cap L^1(\mathbb{R}, \nu)$;
2. $\mu((x, +\infty)) \geq \nu((x, +\infty))$ for every $x \in \mathbb{R}$ and $\mu(\mathbb{R}) = \nu(\mathbb{R})$;
3. $\int h(x)\mu(dx) \leq \int h(x)\nu(dx)$ for every nonincreasing, measurable $h \in L^1(\mathbb{R}, \mu) \cap L^1(\mathbb{R}, \nu)$;
4. $\mu((-\infty, x]) \leq \nu((-\infty, x])$ for every $x \in \mathbb{R}$ and $\mu(\mathbb{R}) = \nu(\mathbb{R})$.

If one of these conditions holds we write $\mu \succeq \nu$.

Moreover the inequality in (1) is strict if and only if there exists $y$ such that $\mu(h^{-1}((y, +\infty)]) < \nu(h^{-1}((y, +\infty)])$ (that is, if and only if there exists $y$ such that $\mu(h^{-1}((y, +\infty)]) < \nu(h^{-1}((y, +\infty)])$).

Finally the inequality in (3) is strict if and only if there exists $y$ such that $\mu(h^{-1}((y, +\infty)]) < \nu(h^{-1}((y, +\infty)])$ (that is, if and only if there exists $y$ such that $\mu(h^{-1}((y, +\infty)]) < \nu(h^{-1}((y, +\infty)])$).
Proof. The equivalence between (1) and (2) (or between (3) and (4)) is a classical result of measure theory: it is a slight modification of the arguments in [43, Section 1.A.1]. Moreover, to prove that $$\mu(\mathbb{R}) = \nu(\mathbb{R})$$ just take condition (1) (or condition (3)) and consider first $$h \equiv 1$$ and then $$h \equiv -1$$. Under $$\mu(\mathbb{R}) = \nu(\mathbb{R})$$ the equivalence between conditions (2) and (4) is trivial. In particular the equivalence between the previous four conditions hold even if we take the set of nonnegative (or nonpositive) measurable functions instead of $$L^1(\mathbb{R}, \mu) \cap L^1(\mathbb{R}, \nu)$$.

Finally note that $$y \mapsto \mu([y, +\infty))$$ and $$y \mapsto \nu([y, +\infty))$$ are continuous from the left while $$y \mapsto \mu((y, +\infty))$$ and $$y \mapsto \nu((y, +\infty))$$ are continuous from the right; this implies that there exists $$y$$ such that $$\mu(h^{-1}([y, +\infty))) < \nu(h^{-1}([y, +\infty)))$$ if and only if there exists $$y'$$ such that $$\mu(h^{-1}((y', +\infty))) < \nu(h^{-1}((y', +\infty)))$$. $\square$

Remark 5.7. Given a random variable $$X$$ with law $$\mu$$, then the composition $$\xi := F_\mu \circ X$$ between the variable and its cumulative distribution function is a random variable with values in $$\text{Rg}(F_\mu) \subseteq [0, 1]$$ such that $$\mathbb{P}(\xi \leq t) \leq t$$ for all $$t \in [0, 1]$$; moreover $$\mathbb{P}(\xi \leq t) = t$$ if and only if $$t \in \text{Rg}(F_\mu) := F_\mu(\mathbb{R})$$. More generally $$\mathbb{P}(\xi \leq t) = \sup \{F_\mu(r) : F_\mu(r) \leq t\}$$, thus if $$\mu(z) > 0$$ then $$\mathbb{P}(\xi \leq t) = \lim_{s \to z-} F_\mu(s) = F_\mu(z) - \mu(z)$$ for all $$t \in [\lim_{s \to z-} F_\mu(s), F_\mu(z)] \equiv [F_\mu(z) - \mu(z), F_\mu(z)]$$.

To be precise if we consider $$\{x: \mu(x) > 0\} =: \{x_i : i \in J\}$$, the at-most-countable set of discontinuity points of $$F_\mu$$ (where $$J \subseteq \mathbb{N}$$), and define $$I := \bigcup_{i \in J} [F_\mu(x_i) - \mu(x_i), F_\mu(x_i))$$ we have

$$F_\xi(t) = \begin{cases} t & \text{if } t \not\in I \\ F_\mu(x_i) - \mu(x_i) & \text{if } t \in [F_\mu(x_i) - \mu(x_i), F_\mu(x_i)) \end{cases}$$

This implies in particular that if $$F_\mu$$ is continuous then the random variable $$\xi$$ is uniformly distributed on $$[0, 1]$$ otherwise, according to Lemma $[5.6]$, $$\xi \succ \text{Unif}(0, 1)$$ (that is, the law of $$\xi$$ stochastically dominates a the uniform distribution on $$[0, 1]$$).

Details on Remark 3.6. For a generic $$f$$, by performing a time rescaling, we can assume without loss of generality that $$\mathbb{T}_f = 1$$. Consider the following family of absolutely continuous (with respect to the Lebesgue measure) measures $$\mu_n(\cdot) = n \cdot \cap [1 - 1/n, 1]$$ with support in $$[0, 1]$$, (where $$\cdot | \cdot$$ represents the Lebesgue measure on $$\mathbb{R}$$). If we define $$c_n(f, p) := \int_0^{1-1/n} f(z) \, dz + p \int_{1-1/n}^1 f(z) \, dz$$ then $$c_n(f, p) \uparrow 1$$ as $$n \to \infty$$ and we have

$$\int_0^1 \phi_{\mu_n}(y) \, d\mu_n(dy) = \int_{1-1/n}^1 e^{-an(y-1+1/n)} \left[ c_n(f, p) + \int_{1-1/n}^y (e^{a(1-p)(z-1+1/n)} - p) f(z) \, dz \right] \, dy \leq \int_{1-1/n}^1 e^{-an(y-1+1/n)} c_n(f, p) \, dy = c_n(f, p) \int_0^1 e^{-ay} \, dy \uparrow \frac{1 - \exp(-a)}{a}$$

as $$n \to \infty$$ (according to the Monotone Convergence Theorem). This example can be modified in many ways: for instance, one can take a family of absolutely continuous measures, with strictly positive densities on $$[0, 1]$$, which approximate the previous densities $$n \mathbb{I}_{[1-1/n, 1]}$$ in the $$L^1$$ norm (we do not give more details on this).
We are left to prove that $\int \phi_\mu(y)\mu(dy) < (1 - \exp(-a))/a$ for all $\mu$. We start by proving that for every measurable, nonincreasing function $h$ and every $z \in \mathbb{R}$ we have $\int_{(z, +\infty)} h(F_\mu(y))\mu(dy) \leq \int_{(F_\mu(z), 1]} h(y)dy$ (and, if $h$ is strictly decreasing on $[0, 1]$, then the inequality is strict if and only if $F_\mu$ is not continuous on $(z, +\infty)$). By stochastic domination (see Remark 5.7), if we denote by $\mathbb{P}_\xi$ the law of $\xi$, $\int \mathbb{P}_\xi(h(F_\mu(y)))\mu(dy) = \int_{[0, 1]} h(s)\mathbb{P}_\xi(ds) \leq \int_{[0, 1]} h(s)ds$ and, for a strictly decreasing function, the inequality is strict if and only if $F_\mu$ is not continuous on $\mathbb{R}$ (apply Lemma 5.6 to $\mathbb{P}_\xi$ and to the uniform distribution on $[0, 1]$ and choose $y := h(s)$ for some $s \in \lim_{w \to z} F_\mu(w)$ whenever this interval is nonempty; note that, for a strictly decreasing function, $h^{-1}([h(s), +\infty)) = (-\infty, s]$ for all $s$). Take $z \in \mathbb{R}$; then

$$\int_{(F_\mu(z), 1]} h(s)\mathbb{P}_\xi(ds) = \int_{F_\mu^{-1}((F_\mu(z), 1])} h(F_\mu(y))\mu(dy) = \int_{(z, +\infty)} h(F_\mu(y))\mu(dy) \tag{5.19}$$

since $F_\mu^{-1}((F_\mu(z), 1]) \supseteq (z, +\infty)$ and $\mu(F_\mu^{-1}((F_\mu(z), 1]) \setminus (z, +\infty)) = 0$.

By the previous equation we just need to prove that $\int_{(F_\mu(z), 1]} h(s)\mathbb{P}_\xi(ds) \leq \int_{(F_\mu(z), 1]} h(s)ds$ and this can be done in two different ways.

The quick way is to note that, according to Remark 5.7, $\mathbb{P}_\xi([0, F_\mu(z)])$ equals $F_\mu(z)$, that is, the Lebesgue measure of the interval $[0, F_\mu(z)]$; hence the measure $\mathbb{P}_\xi$ restricted to $(F_\mu(z), 1]$ dominates the Lebesgue measure on the same interval, thus Lemma 5.6 applies.

An alternate proof is as follows; if we define

$$\bar{h}(y) := \begin{cases} h(s) & \text{if } s \geq F_\mu(z) \\ h(F_\mu(z)) & \text{if } s < F_\mu(z) \end{cases}$$

then $\bar{h}$ is nonincreasing hence, by stochastic domination, $\int_{\mathbb{R}} \bar{h}(F_\mu(y))\mu(dy) \leq \int_{[0, 1]} \bar{h}(s)ds$. Thus

$$\int_{(z, +\infty)} h(F_\mu(y))\mu(dy) = \int_{(z, +\infty)} \bar{h}(F_\mu(y))\mu(dy) = \int_{\mathbb{R}} \bar{h}(F_\mu(y))\mu(dy) - \int_{(-\infty, z]} \bar{h}(F_\mu(y))\mu(dy)$$

$$= \int_{\mathbb{R}} \bar{h}(F_\mu(y))\mu(dy) - \bar{h}(F_\mu(z))\mu((-\infty, z])$$

$$\leq \int_{[0, 1]} \bar{h}(s)ds - \bar{h}(F_\mu(z))\mu((-\infty, z]) = \int_{[0, 1]} \bar{h}(s)ds - \bar{h}(F_\mu(z))F_\mu(z)$$

$$= \int_{[0, 1]} \bar{h}(s)ds - \int_{[0, F_\mu(z)]} \bar{h}(s)ds$$

$$= \int_{(F_\mu(z), 1]} \bar{h}(y)dy = \int_{(F_\mu(z), 1]} h(y)dy \tag{5.20}$$

and, if $h$ is strictly decreasing on $[0, 1]$, the inequality is strict if and only if $F_\mu$ is not continuous on $(z, +\infty)$ (since $\bar{h}$ is strictly decreasing on $[F_\mu(z), 1]$ we use equation (5.19) and we can apply again Lemma 5.6 to $\mathbb{P}_\xi$ and to the uniform distribution on $[0, 1]$ by choosing $y := h(s)$ for some $s \in \lim_{w \to z} F_\mu(w)$ and $F_\mu(\bar{z})$ whenever this interval is nonempty and $\bar{z} \in (z + \infty)$).

31
Clearly
\[
\int \phi_\mu(y) \mu(dy) = \mathbb{E} \left[ \exp(-a\xi) \left( \int_0^X \exp(a(1-p)F_\mu(z))f(z)dz + p \int_0^{\bar{t}_f} f(z)dz \right) \right].
\]

Hence, using Fubini’s Theorem and the inequality (5.20) with \( h(s) := e^{-as} \), we have
\[
\int \phi_\mu(y) \mu(dy) = \int e^{-aF_\mu(y)} \left[ \int_0^y (e^{a(1-p)F_\mu(z)} - p) f(z)dz + p \right] \mu(dy)
\]
\[
= p \int e^{-aF_\mu(y)} \mu(dy) + \int (e^{a(1-p)F_\mu(z)} - p) f(z) \int_{(z, +\infty)} e^{-aF_\mu(y)} \mu(dy)dz
\]
\[
\leq p \int_{[0, 1]} e^{-ay}dy + \int (e^{a(1-p)F_\mu(z)} - p) \int_{(F_\mu(z), 1]} e^{-ay}dydz
\]
\[
= \frac{1 - e^{-a}}{a} + \int (e^{a(1-p)F_\mu(z)} - p) f(z) \frac{e^{-aF_\mu(z)} - e^{-a}}{a}dz
\]
\[
= \frac{1 - e^{-a}}{a} + \int (e^{-apF_\mu(z)} - pe^{-aF_\mu(z)}) f(z) \frac{1 - e^{-a(1-F_\mu(z))}}{a}dz = (**)
\]
and the inequality is strict if and only if \( F_\mu \) is not continuous. Now \( (1-e^{-a(1-F_\mu(z))})/a \leq (1-e^{-a})/a \) and \( e^{-apF_\mu(z)} - pe^{-aF_\mu(z)} \leq 1 - p \) (since \( s \mapsto e^{-ap} - pe^{-as} \) is decreasing in \([0, +\infty)\)); moreover each of the previous inequalities become a strict inequality if and only if \( F_\mu(z) > 0 \). Whence
\[ (** \leq p \frac{1 - e^{-a}}{a} + (1 - p) \frac{1 - e^{-a}}{a} \]
and there is a strict inequality if and only if \( \inf \text{supp}(\mu) < \sup \text{Esupp}(f) \).

Proof of Proposition \ref{proposition.:} 1. Applying Proposition \ref{proposition.5.8}, we have easily that \( \int_0^y f_1(x)dx \geq \int_0^y f_2(x)dx \) for all \( z \leq y, y \in [t_1, t_2] \), hence \( \phi_\mu^{(1)}(y) \geq \phi_\mu^{(2)}(y) \).

2. If \( t_2 \geq \bar{t}_1 \) the conclusion follows from Proposition \ref{proposition.3.7}(1). Let us suppose \( t_2 < \bar{t}_1 \). Now let us evaluate \( \phi_\mu^{(2)}(y) \) for \( y \in [t_2, \bar{t}_1] \):
\[
\phi_\mu^{(2)}(y) = \exp(-aF_\mu(y)) \int_{t_2}^y \exp(a(1-p)F_\mu(x)) f_2(x)dx + p \exp(-aF_\mu(y)) \mathbb{P}(D_2 \in [y, \bar{t}_1])
\]
\[
+ p \exp(-a) \mathbb{P}(D_2 \geq \bar{t}_1) = (*).
\]
Note that this equality holds even if \( \bar{t}_1 \geq t_2 \) since in that case \( \mathbb{P}(D_2 \geq \bar{t}_1) = 0 \).
\[ (*) \leq \exp(-apF_\mu(y)) \mathbb{P}(D_2 \in [t_2, y]) + p \exp(-aF_\mu(y)) \mathbb{P}(D_2 \in [y, \bar{t}_1]) + p \exp(-a) \mathbb{P}(D_2 \geq \bar{t}_1)
\]
\[ \leq \mathbb{P}(D_2 \in [t_2, t_1]) + p \exp(-a) \mathbb{P}(D_2 \geq \bar{t}_1)
\]
which is smaller than \( \exp(-a) \) if \( \mathbb{P}(D_2 \in [t_2, \bar{t}_1]) \) is sufficiently small. When \( \mu \) is an ESS, then for all \( y \in [\bar{t}_1, \bar{t}_1] \) we have \( \phi_\mu^{(1)}(y) = \lambda(a, p) \geq \exp(-a) \). If \( t_2 \leq \bar{t}_1 \) then the proof is complete. If \( t_2 > \bar{t}_1 \) then the conclusion follows using Proposition \ref{proposition.3.7}(1) for \( y \in [t_1, t_2] \).
3. Consider the solution \( y_1 \) to the equation \((y - t_1)/(t_1 - t_1) = (y - t_2)/(t_2 - t_2)\), namely \( y_1 := (t_2t_1 - t_1^2)/(t_2 - t_1)\); clearly for all \( y \geq y_1 \) we have \((y - t_1)/(t_1 - t_1) \leq (y - t_2)/(t_2 - t_2)\), thus Proposition 5.8 implies \( \phi^{(2)}_\mu(y) \geq \phi^{(1)}_\mu(y) \).

Proposition 5.8. Consider two probability densities \( f_1 \) and \( f_2 \). Let us define \( \phi^{(1)}_\mu \) and \( \phi^{(2)}_\mu \) according to equation (2.1) using \( f_1 \) and \( f_2 \) respectively. Fix \( y > 0 \) such that \( \int_0^y f_1(x)dx > 0 \) or \( \int_0^y f_2(x)dx > 0 \).

1. Define the set of strong maxima from the left of \( F_\mu \) as \( M_\mu(y) := \{ z \in [0, y] : F_\mu(s) < F_\mu(z) \text{ for all } s < z \} \). If

\[
\int_z^y f_1(x)dx \geq \int_z^y f_2(x)dx, \quad \forall z \in M_\mu(y)
\]

then \( \phi^{(1)}_\mu(y) \geq \phi^{(2)}_\mu(y) \). In this case \( \phi^{(1)}_\mu(y) = \phi^{(2)}_\mu(y) \) if and only if equality holds in equation (5.21) for all \( z \in M_\mu(y) \).

2. If \( \int_0^y f_1(x)dx > \int_0^y f_2(x)dx \) and \( a \) is sufficiently small then \( \phi^{(1)}_\mu(y) > \phi^{(2)}_\mu(y) \).

Proof of Proposition 5.8. According to equation (2.1) we have

\[
\phi^{(i)}_\mu(y) = \exp(-aF_\mu(y)) \left[ \int_0^y (\exp(a(1-p)F_\mu(x)) - p) f_i(x)dx + p \right], \quad i = 1, 2.
\]

1. We just need to prove that \( \int_0^y (\exp(a(1-p)F_\mu(x)) - p) f_1(x)dx \geq \int_0^y (\exp(a(1-p)F_\mu(x)) - p) f_2(x)dx \). This follows easily from the fact that \( x \mapsto \exp(a(1-p)F_\mu(x)) - p \) is a nondecreasing function and applying Fubini’s Theorem. Indeed, for every \( z \geq 0 \), the set \( \{ x \geq 0 : \exp(a(1-p)F_\mu(x)) - p \leq z \} \) is an interval of type \([x_0(z), y] \) (for some \( x_0(z) \in [0, y] \)); clearly \( x_0(z) = 0 \) for all \( z \in [0, 1-p] \). Hence

\[
\int_0^y (\exp(a(1-p)F_\mu(x)) - p) f_i(x)dx = \int_0^{\exp(a(1-p)F_\mu(y)) - p} \left[ \int_{\{x \in \mathbb{R} : \exp(a(1-p)F_\mu(x)) - p \geq z \}} f_i(x)dx \right] dz
\]

\[
= \int_0^{\exp(a(1-p)F_\mu(y)) - p} \left[ \int_{\{x_0(z), y\}} f_i(x)dx \right] dz \quad \text{(5.22)}
\]

\[
= (1-p) \int_{[0,y]} f_i(x)dx + \int_1^{\exp(a(1-p)F_\mu(y)) - p} \left[ \int_{\{x_0(z), y\}} f_i(x)dx \right] dz. \]

The equivalence of the equalities is as follows. The “if” part is trivial. As for the reverse implication, note that \( z \mapsto x_0(z) \) is left-continuous and that \( s = x_0(z) \) for some \( z \in [0, \exp(a(1-p)F_\mu(y)) - p] \) if and only if \( s = \inf \{ t \geq 0 : F_\mu(t) \geq \alpha \} \) for some \( \alpha \leq F_\mu(y) \),
Proof of Proposition 3.9. By using some basic results of mathematical analysis, it is easy to check that

1. It follows from the first part of Proposition 3.7.

2. It follows from equation (5.22).

Proof of Proposition 3.8.

From equation (5.20) we have

\[
\int_{(z, +\infty)} e^{-aF_\mu(y)} \mu(\text{d}y) \leq \int_{(F_\mu(z), 1]} e^{-ay} \text{d}y = \frac{e^{-aF_\mu(z)} - e^{-a}}{a}. \tag{5.23}
\]

that is, if and only if \( x_0(z) \in M_\mu(y) \). If \( \int_0^y f_1(x) \text{d}x > \int_0^y f_2(x) \text{d}x \) then \( \phi^{(1)}_\mu(y) > \phi^{(2)}_\mu(y) \) follows from equation (5.22). If \( \int_{x_0(z)}^y f_1(x) \text{d}x > \int_{x_0(z)}^y f_2(x) \text{d}x \) for some \( x_0(z) > 0 \) then by the continuity of \( w \mapsto \int_w^y f_1(x) \text{d}x \) and the left continuity of \( z \mapsto x_0(z) \) there exists \( \varepsilon > 0 \) such that \( \int_{x_0(s)}^y f_1(x) \text{d}x > \int_{x_0(s)}^y f_2(x) \text{d}x \) for all \( s \in (z - \varepsilon, z] \); again equation (5.22) yields the strict inequality \( \phi^{(1)}_\mu(y) > \phi^{(2)}_\mu(y) \).

2. It follows from equation (5.22)

\[
\phi^{(1)}_\mu(y) - \phi^{(2)}_\mu(y) \geq (1 - p) \int_{[0,y]} (f_1(x) - f_2(x)) \text{d}x - (\exp(a(1-p)F_\mu(y)) - 1).
\]

by taking the limit as \( a \) goes to 0.

\[ \square \]

Proof of Proposition 3.8. 1. It follows from the first part of Proposition 3.7.

2. If \( t_1 > t_2 \) then, by Remark 3.6, \( \lambda^{(2)}_\mu = (1 - \exp(-a))/a \), which is larger than \( \lambda^{(1)}_\mu \) and the proof is complete. If \( t_1 \leq t_2 \), write \( \lambda^{(1)}_\mu = (1 - \exp(-a))/a - \varepsilon \). Note that, if \( y \geq t_2 \), then \( \phi^{(2)}_\mu(y) = \exp(-aF_\mu(y)) \int_{t_2}^{t_2} \exp(a(1-p)F_\mu(x)) f_2(x) \text{d}x \). Thus, if we integrate with respect to \( \mu \):

\[
\lambda^{(2)}_\mu \geq \int_{t_2}^{t_1} \phi^{(2)}_\mu(y) \text{d}\mu(y)
\]

\[
= \frac{1}{a} (\exp(-aF(t_2)) - \exp(-a)) \left( \int_{t_2}^{t_1} f_2(x) \text{d}x + \int_{t_2}^{t_1} \exp(a(1-p)F_\mu(x)) f_2(x) \text{d}x \right)
\]

\[
\geq \frac{1}{a} (\exp(-aF(t_2)) - \exp(-a)) \geq \frac{1}{a} (1 - \exp(-a)) - \varepsilon
\]

where the last inequality holds if \( F_\mu(t_2) \) is sufficiently small.

\[ \square \]

Proof of Proposition 3.9. By using some basic results of mathematical analysis, it is easy to check that \( \partial_p \int \phi_\mu(y) \mu(\text{d}y) = \int \partial_p \phi_\mu(y) \mu(\text{d}y) \) where, from equation (2.1),

\[
\partial_p \phi_\mu(y) = \exp(-aF_\mu(y)) \left[ -a \int_0^y \exp(a(1-p)F_\mu(x)) F_\mu(x) f(x) \text{d}x + \int_y^{t_f} f(x) \text{d}x \right].
\]

From equation (5.20) we have

\[
\int_{(z, +\infty)} e^{-aF_\mu(y)} \mu(\text{d}y) \leq \int_{(F_\mu(z), 1]} e^{-ay} \text{d}y = \frac{e^{-aF_\mu(z)} - e^{-a}}{a}. \tag{5.23}
\]
According to Fubini-Tonelli’s Theorem

\[
\partial_p \bar{\lambda}_\mu = \partial_p \int \phi_\mu(y) \mu(dy) = \int \partial_p \phi_\mu(y) \mu(dy)
\]

\[
= -a \int_0^{\bar{\tau}_f} e^{a(1-p)F_\mu(x)} F_\mu(x) f(x) \left( \int_{(x,+\infty)} e^{-aF_\mu(y)} \mu(dy) \right) dx
\]

\[
+ \int_0^{\bar{\tau}_f} f(x) \left( \int_{[0,x]} e^{-aF_\mu(y)} \mu(dy) \right) dx
\]

\[
= \int_0^{\bar{\tau}_f} f(x) \left[ \int_{[0,x]} e^{-aF_\mu(y)} \mu(dy) - ae^{a(1-p)F_\mu(x)} F_\mu(x) \left( \int_{(x,+\infty)} e^{-aF_\mu(y)} \mu(dy) \right) \right] dx
\]

Let us study the expression between brackets by means of the function \( \bar{h}_p \) defined by the following equation

\[
h_p(x) := \int_{[0,x]} e^{-aF_\mu(y)} \mu(dy) - ae^{a(1-p)F_\mu(x)} F_\mu(x) \left( \int_{(x,+\infty)} e^{-aF_\mu(y)} \mu(dy) \right) \geq \int_{[0,x]} e^{-aF_\mu(y)} \mu(dy) - ae^{a(1-p)F_\mu(x)} F_\mu(x) (1 - e^{-aF_\mu(x)}) =: \bar{h}_p(x)
\]

which holds for every \( x \in [0,\bar{\tau}_f], p \in [0,1] \) (the inequality comes from equation (5.23)). Clearly \( p \mapsto \bar{h}_p(x) \) is nondecreasing hence \( \bar{h}_p(x) \geq \bar{h}_0(x) \) for all \( x \in [0,\bar{\tau}_f] \). In particular \( p \mapsto \bar{h}_p(x) \) is strictly increasing if \( F_\mu(x) > 0 \); in this case \( \bar{h}_p(x) > \bar{h}_0(x) \). Suppose that \( a \leq 2 \log(2) \); thus \( e^{-az} + e^{-a(1-z)} \geq 2e^{-a/2} \geq 1 \). Now, since \( F_\mu(0) = \mu(0) \),

\[
\bar{h}_0(0) = \mu(0)e^{-a\mu(0)} - \mu(0)(1 - e^{-a(1-\mu(0))}) = \mu(0)(e^{-a\mu(0)} + e^{-a(1-\mu(0))} - 1) \geq 0.
\]

Moreover, if \( z \geq x \geq 0 \) we have

\[
\bar{h}_0(z) - \bar{h}_0(x) = \int_{[x,z]} e^{-aF_\mu(y)} \mu(dy) - F_\mu(z) \left( 1 - e^{-a(1-F_\mu(z))} \right) + F_\mu(x) \left( 1 - e^{-a(1-F_\mu(x))} \right)
\]

\[
= \int_{[x,z]} e^{-aF_\mu(y)} \mu(dy) - (F_\mu(z) - F_\mu(x)) \left( 1 - e^{-a(1-F_\mu(z))} \right)
\]

\[
+ F_\mu(x) \left( e^{-a(1-F_\mu(z))} - e^{-a(1-F_\mu(x))} \right)
\]

\[
\geq (F_\mu(z) - F_\mu(x))(e^{-aF_\mu(z)} + e^{-a(1-F_\mu(z))} - 1)
\]

\[
+ F_\mu(x)(e^{-a(1-F_\mu(z))} - e^{-a(1-F_\mu(x))}) \geq 0
\]

where the last inequality is strict if and only if \( F_\mu(z) > F_\mu(x) \) (we also used the fact that \( \int_{[x,z]} e^{-aF_\mu(y)} \mu(dy) \geq e^{-aF_\mu(z)} \mu((x,z]) = e^{-aF_\mu(z)} (F_\mu(z) - F_\mu(x)) \)). This means that, for all \( x \in [0,\bar{\tau}_f], p \in [0,1] \) we have \( \bar{h}_p(x) \geq \bar{h}_p(0) \geq \bar{h}_0(0) \geq 0 \). Observe that \( \partial_p \bar{\lambda}_\mu(a,p,\mu,f) = \int_0^{\bar{\tau}_f} f(x) \bar{h}_p(x) dx \). Whence, for all \( a \leq 2 \log(2) \), for all \( \mu \) and for all \( f \), we have that \( \partial_p \bar{\lambda}_\mu(a,p,\mu,f) \geq 0 \) for all \( p \in [0,1] \).

Observe that \( F_\mu(x) = 0 \) for all \( x < \bar{\tau}_f \) if and only if \( \bar{\tau}_f > \inf \supp(\mu) \). Hence, if \( F_\mu(x) = 0 \) for all \( x < \bar{\tau}_f \) clearly \( \phi_\mu(y) = 1 \) for all \( y \in \supp(\mu) \) which implies \( \bar{\lambda}_\mu(a,p,\mu,f) = 1 \) for all \( p \in [0,1] \).
On the other hand if $F_{\mu}(x) > 0$ for some $x < \bar{t}_f$ we have that $h_p(z) > 0$ for every $z \in [x, \bar{t}_f]$, $p \in (0, 1]$; thus for all $a \leq 2 \log(2)$, for all $\mu$ and for all $f$, we have that $\partial_p \lambda_{\mu}(a, p, \mu, f) > 0$ for all $p \in (0, 1]$.
