Role of Radical Prostatectomy for High-Risk Prostate Cancer

Dalsan You, In Gab Jeong, Choung-Soo Kim
Department of Urology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea

High-risk localized prostate cancer traditionally includes patients with clinical T3 disease but also includes those with apparently localized disease but with adverse prognostic factors such as a Gleason score of 8 to 10, prostate-specific antigen of more than 20 ng/ml, or extensive disease on biopsy. In the past, these patients were treated primarily with radiation therapy due to concerns that surgery was not likely to be curative and was associated with a high incidence of side-effects. In addition, the lack of randomized trials comparing curative treatments for high-risk prostate cancer makes treatment decisions in this patient population difficult. Several retrospective series have reported the long-term efficacy of radical prostatectomy monotherapy in a high-risk population, showing that the 5-year cancer-specific survival rate was more than 80% and the 5-year biochemical recurrence-free survival rate was about 50%. In addition, comparisons of different treatment options by means of nonrandomized trials have shown improved outcomes with surgery compared with radiation therapy or observation. Thus, there is renewed interest in radical prostatectomy as the primary treatment for patients with high-risk prostate cancer. Here, we reviewed the outcomes of radical prostatectomy, with or without neoadjuvant or adjuvant therapies, in high-risk patients and what is known about the choice and timing of adjuvant therapies.

Key Words: Prostatectomy; Prostatic neoplasms; Risk assessment

INTRODUCTION

The wide application of prostate-specific antigen (PSA) screening has led not only to a higher incidence of prostate cancer, but also to a profound stage migration [1]. With this remarkable stage migration, 91% of cases are being detected as clinically localized prostate cancer, whereas the proportion of metastatic disease at the time of diagnosis was just 4% in the United States in 2009 [2]. Because the natural history of clinically localized prostate cancer varies from indolent disease to highly aggressive disease, the risk stratification of disease poses a significant challenge to the physician who treats patients with clinically localized prostate cancer. The potential aggressiveness of each tumor and the general health, life expectancy, and quality of life preferences of each patient must be assessed prior to selecting treatment. Although the optimal treatment for clinically localized prostate cancer has not been established because of a lack of randomized controlled trials, both radical prostatectomy (RP) and radiation therapy (RT) have excellent outcomes for low- and intermediate-risk disease. However, there is no consensus on the optimal treatment for high-risk localized prostate cancer, and much debate exists regarding the ideal treatment approach [3]. Most urologists recommend androgen-deprivation therapy (ADT) plus external-beam radiation therapy (EBRT), with only about 36% of high-risk patients initially treated with RP [4]. The aim of this article is to enable physicians to identify patients with high-risk localized prostate cancer and to review current data on the role of RP monotherapy for these patients. We have also reviewed current data about multi-modality therapies for patients with high-risk prostate cancer, including RP combined with neoadjuvant or adjuvant ADT and/or RT.

DEFINITION OF HIGH-RISK PROSTATE CANCER

Pretreatment risk stratification of newly diagnosed, clin-
Physically localized prostate cancer to predict the likelihood of treatment failure is essential for counseling and informed decision making. The risk of relapse following therapy has been estimated by using multiple definitions ranging from a single parameter, including clinical stage [5], biopsy Gleason score (GS) [6], and PSA [7], to a combination of variables [8] to scoring systems [9] or nomogram definition [10].

To date, however, there is no universally accepted definition of high-risk prostate cancer, and not all clinically high-risk prostate cancers defined by a single parameter are pathologically high-risk prostate cancers with a high likelihood of progression. Clinical staging by digital rectal examination failed to detect extraprostatic extension in 24% of patients [11] and over-staged organ-confined disease in 27% [5]. Poorly differentiated prostate cancer on biopsy is often downgraded in the final RP specimen [12]. Although high PSA concentration may be indicative of tumor burden, it may also be high due to benign prostatic hyperplasia or inflammation [13].

The most commonly accepted definition was proposed by D’Amico et al and defines high-risk prostate cancer as PSA more than 20 ng/ml or GS of 8 to 10 or clinical stage of at least T2c [8]. The proportion of patients presenting with high-risk prostate cancer by this definition decreased from 40.9% in 1989 to 1990 to 14.8% in 2001 to 2002. The downward stage migration due to widespread PSA screening resulted in a significant shift in the determinants of prostate cancer risk stratification, with GS now more likely and PSA less likely to drive risk assignment [14]. The high-risk definition proposed by D’Amico et al is also used in the European Association of Urology (EAU) guidelines on prostate cancer [3]. The 2010 National Comprehensive Cancer Network (NCCN) guidelines define patients with clinically localized, high-risk disease as those with clinical stage T3a disease, GS 8 to 10, or PSA more than 20 ng/ml and very-high-risk patients as those with clinical stage T3b-T4 disease [15].

The definition of high-risk prostate cancer influences the prediction of extraprostatic disease and treatment outcome. For example, a study of the relationships among various definitions of high-risk prostate cancer and the pathological characteristics of RP specimens and PSA relapse after RP found that, depending on its definition, 22-63% of patients had pathologically organ-confined disease, which is surgically curable with RP monotherapy or as part of a multimodal approach [16]. The risk of PSA relapse clearly varies related to the definition used. From 41% to 74% of the patients remained progression-free at 10 years after RP. The 10-year progression-free probability rate ranged from 41% (the lowest) in 1992 TNM clinical T3 and 74% (the highest) in the patients with high-risk cancer defined by a preoperative PSA velocity more than 2 ng/ml/year (Fig. 1).

**NATURAL HISTORY OF HIGH-RISK PROSTATE CANCER**

It is difficult to determine the natural history of high-risk prostate cancer. Because long-term survival rates are high in patients with prostate cancer, it is difficult to compare survival rates among risk groups. In addition, patients with high-risk prostate cancer are rarely allocated to active surveillance in contemporary cohorts. Several studies, however, can provide insights into the natural history of high-risk prostate cancer.

In a prospective cohort study before the PSA era, Johansson et al described the natural history of initially untreated prostate cancer [17]. In the clinically localized group (clinical stage of T2 or less), the corrected 15-year overall survival rate was similar in patients with deferred treatment and in patients who received initial treatment (81% for both groups). Moreover, although prostate cancer accounted for 37% of all deaths, only 11% of patients with localized disease died due to prostate cancer. But the corrected 15-year overall survival was 57% in patients with locally advanced prostate cancer (clinical stage of T3-T4). Those authors concluded that patients with locally advanced disease need trials of aggressive therapy to improve their poor prognosis.

Reviews of two population-based cohorts of men with localized prostate cancer in the Connecticut Tumor Registry show the changes resulting from the introduction of widespread PSA testing [18,19]. The first cohort consisted of patients diagnosed with prostate cancer between 1971 and 1984 before the advent of PSA testing, whereas the second cohort consisted of men diagnosed with prostate cancer between 1990 and 1992, at the start of widespread PSA testing.
The first cohort consisted of 767 men with clinically localized prostate cancer who underwent watchful waiting alone [18]. The 15-year cancer-specific mortality rate in men with GS 6 was 18% to 30%, compared with a 25% to 59% risk of death from other causes. The mortality rates from prostate cancer were higher in patients with GS 7 (42% to 70%) and GS 8-10 (60% to 87%).

In the second population-based cohort, the authors examined the survival of men 75 years or younger who had clinically localized prostate cancer, comparing those treated with RP, EBRT, or observation [19]. Patients were stratified according to several methods, to control for both known and unknown confounding factors. The cancer-specific mortality rates in high-risk patients by the D'Amico classification, were 2.3- and 3.4-fold higher in the RT and observation groups, respectively, than in the RP group. The estimated 10-year cancer-specific survival rates in patients in the RP, EBRT, and observation groups were 90%, 80%, and 70%, respectively, for those with high-risk prostate cancer.

These results suggest that patients with high-risk prostate cancer are at significant risk of disease progression and cancer-specific deaths if left untreated and that RP may provide a survival advantage over EBRT or observation.

RADIATION THERAPY WITH OR WITHOUT ANDROGEN DEPRIVATION THERAPY

The RT dose for the management of low-risk prostate cancer is recommended to be at least 72 Gy by the EAU guidelines [3], and ranges from 70 to 79 Gy according to the 2010 NCCN guidelines [15]. The results of an M.D. Anderson Cancer Center trial showed that in patients with high-risk prostate cancer, dose escalation up to 78 Gy improves the results [20,21]. The 8-year biochemical recurrence-free rate was superior for the 78 Gy arm than for the 70 Gy arm (78% vs. 59%, p=0.004), and the benefit was even greater in patients with an initial PSA more than 10 ng/ml (78% vs. 39%, p=0.001). Moreover, the 8-year clinical failure rate was significantly lower in the 78 Gy arm than in the 70 Gy arm (7% vs. 15%, p=0.014), although the incidence of grade 2 or higher gastrointestinal toxicity was twice as high in the 78 Gy arm (26% vs. 13%) [21].

Because EBRT is insufficient to cover the tumor beyond the pelvis, the benefit of adjuvant ADT was prospectively evaluated [22,23]. In a randomized, prospective trial of patients with locally advanced prostate cancer, the 5-year clinical disease-free survival rate was significantly higher in patients treated with 70 Gy EBRT plus 3 years of ADT than in those treated with 70 Gy EBRT alone (74% vs. 40%, p=0.0001), as were the 5-year overall survival rate (79% vs. 62%, p=0.0002) and 5-year cancer-specific survival rate (94% vs. 79%, p=0.0001) [23].

Based on these findings, the 2010 NCCN guidelines suggest that RT doses between 78 and 80 + Gy improve PSA-assessed disease control in patients with intermediate- or high-risk [15]. Moreover, these guidelines recommend patients with high-risk disease as candidates for pelvic lymph node irradiation and neoadjuvant/concomitant/adjuvant ADT for 2 to 3 years.

RADICAL PROSTATECTOMY MONOTHERAPY

There are two primary goals of treatment for patients with high-risk prostate cancer. The first is long-term cure, defined as undetectable PSA or biochemical recurrence-free survival; although, due to the slow progression of prostate cancer, alternate definitions of cure are encompassed in metastasis-free survival and cancer-specific survival. The second goal is local disease control. Locally progressive prostate cancer can cause recurrent hematuria, urinary retention, pain, and hydronephrosis, the relief of which requires palliative surgical intervention.

RP has been regarded as technically difficult in patients with high-risk prostate cancer and associated with high incidences of side effects, including frequent incontinence. A prospective study, however, found that the recovery and continence rates following RP were similar in patients with locally advanced and low-risk prostate cancer [24]. Table 1 summarizes the oncologic outcome in patients with high-risk prostate cancer treated with RP monotherapy.

A pooled analysis of 298 patients with clinical T3 disease, only 27 (9%) with organ-confined disease, treated with RP monotherapy at several institutions in the United States and Europe found that the 5-year biochemical recurrence-free survival rates were 16% to 29% for patients with low-grade tumors versus 11% for patients with high-grade tu-

| No. of patients | Definition | Organ-confined disease (%) | 5-year BCR-free survival rate (%) | 8-year BCR-free survival rate (%) | 10-year BCR-free survival rate (%) | 10-year CSS rate (%) |

Individual patients with locally advanced prostate cancer.

PSA.

diagnosis and failure to reach undetectable postoperative

and survival in patients with high PSA concentrations at

indicated that GS was a powerful predictor of recurrence

rates were 85% and 72%, respectively [26]. These findings

was 71% and the 5- and 10-year cancer-specific survival

fined disease, found that the 5-year rate of PSA progression

sitive disease, found that the 15-year biochemical recurrence-free, meta-

stasis-free, metastasis-free, and cancer-spe-

and 6% died due to prostate cancer [30]. The 10-year bio-

ly with RP monotherapy found that, at a median follow-up

found that the 15-year biochemical recurrence-free, meta-

stasis-free, and cancer-specific survival rates were 49%,

73%, and 84%, respectively [29]. Among the 28 patients

with PSA recurrence, a PSA doubling time < 9 months was

significantly associated with increased risk of prostate
cancer deaths. These findings indicated that RP alone pro-

vided long-term cancer control in about half of these men

and that the PSA doubling time at the time of recurrence

is a useful determinant of risk of prostate cancer deaths

among patients with PSA recurrence.

A study of outcomes in 175 high-risk patients treated main-

ly with RP monotherapy found that, at a median follow-up

of 8 years, 29% experienced biochemical progression, 3.4%

had local recurrence, 13% developed metastatic disease,

and 6% died due to prostate cancer [30]. The 10-year bio-

chemical recurrence-free, metastasis-free, and cancer-spe-
cific survival rates were 68%, 84%, and 92%, respectively.

Taken together, the results of all of these studies show that

49-68% of patients with locally advanced prostate cancer

were shown to achieve prolonged disease-free survival

with RP alone [29,30]. More refined risk assessments are

needed to determine whether surgical intervention alone

or in combination with other therapies is optimal in in-

dividual patients with locally advanced prostate cancer.

MULTI-MODALITY THERAPY INCLUDING

RADICAL PROSTATECTOMY

Regardless of the definition of high-risk prostate cancer, a

substantial proportion of these patients require a multi-

modality treatment approach that includes both local and

systemic therapies. In recent years, several series of such

multiple treatment approaches have been published, and

RP has been shown to provide an excellent foundation for

oncologic control of these patients. The 2010 NCCN guide-

lines recommend RP with pelvic lymph node dissection for

selected patients with high-risk or very-high-risk prostate

cancer without fixation to adjacent organs [15].

1. Neoadjuvant hormone therapy

The vast majority of patients will respond to initial hormon-

al therapy, showing a significant shrinkage in the extent of

the palpable tumor and a drop in serum PSA concentration.

For example, the SWOG 9109 trial reported 5-year out-

comes in 55 patients with clinical T3-T4 prostate cancer

treated with 4 months of neoadjuvant hormone therapy fol-

lowed by RP [31]. Nearly all patients showed significant

shrinkage of the palpable tumor, and PSA was undetectable

in 55%. RP was feasible in all 55 patients, with acceptable

complications, with rectal injury occurring in only 1 patient.

Approximately 80% of these patients became completely

continent with no pads. Histological examination of the RP

specimens revealed positive nodes in 19%, seminal vesicle

invasion in 30%, and positive surgical margins in 30%.

Despite this worrisome pathology, PSA remained undetec-
table in 70% of these patients after 5 years.

Neoadjuvant hormonal therapy prior to RP was found to

significantly reduce the proportion of patients with pos-
tive surgical margins (odds ratio [OR]: 0.34, 95% con-

fidence interval [CI]: 0.27-0.42, p < 0.00001) and to im-

prove other pathological variables such as lymph node in-

volvement, pathological staging, and organ-confined rates.

In addition, there was a borderline significant reduction in

disease recurrence rate (OR: 0.74, 95% CI: 0.55-1.0, p=0.05)

[32]. Neoadjuvant hormonal therapy, however, did not sig-

ificantly increase overall and progression-free survival

rates.

Despite the lack of absolute evidence of efficacy, many

urologists use neoadjuvant hormonal therapy in patients

with clinical T3 disease for two reasons. First, it may make

a potentially difficult surgery technically easier, perhaps

improving the likelihood of obtaining negative surgical

margins. Second, it cannot hurt and may even enhance a

patient’s chance of long-term cure [33]. Nevertheless, neo-

adjuvant ADT for RP is strongly discouraged in the 2010

NCCN guidelines [15].

2. Adjuvant radiation therapy

Although it seems logical that RT should improve cure

rates after RP for patients with adverse pathological fea-
tures, nonrandomized studies showed no survival advant-

age despite improved local control [34]. Analysis of the effi-
cacy of adjuvant RT in patients with undetectable PSA and

salvage RT in patients with increasing PSA has shown that

biochemical recurrence-free survival rate is maximal in pa-

tients with undetectable PSA after RP [35,36]. These find-
ings highlight the importance of the early application of combined modality treatment, when the tumor burden is at its lowest value and the likelihood of multiple sites of metastases is reduced.

Two prospective, randomized controlled trials (EORTC 22911 and SWOG 8794) have assessed the effectiveness of adjuvant RT. In the EORTC 22911 trial, 1,005 patients with a positive surgical margin or pT3 disease were randomly assigned to adjuvant EBRT (60-65 Gy) or no adjuvant EBRT [37]. The 5-year biochemical progression-free survival (74% vs. 53%) and clinical progression-free survival (85% vs. 8%) were higher in patients receiving adjuvant EBRT, but there were no significant differences in 5-year metastasis-free survival, cancer-specific survival, and overall survival rates. In the SWOG 8,794 trial, 425 patients with high-risk localized prostate cancer were randomly assigned to adjuvant EBRT (60-65 Gy) or observation only [38]. The median PSA relapse-free survival (13.8 vs. 10.3 years) and recurrence-free survival (9.9 vs. 3.1 years) periods were greater in the EBRT group. At a median follow-up of 10.6 years, the cancer-specific mortality and overall survival rates were significantly greater in the adjuvant EBRT arm. The results of these two trials suggest that adjuvant EBRT immediately after RP improved biochemical recurrence-free survival and local control in patients with pathologically advanced prostate cancer who are at high risk of progression. However, the ability of adjuvant EBRT to enhance metastasis-free survival and overall survival is unclear.

3. Salvage radiotherapy
A large retrospective study of 501 patients treated with salvage RT showed that the 4-year progression-free rate was 45% [39]. Factors associated with poor response included preradiotherapy PSA more than 2 ng/ml, GS 8 to 10, PSA doubling time less than 10 months, negative tumor margins, and seminal vesicle invasion. Salvage EBRT can produce good responses in patients with preradiotherapy PSA is less than 1.0 ng/ml, or it may be better to start salvage RT as soon as biochemical recurrence is indicated.

4. Adjuvant hormone therapy
The use of hormonal therapy in high-risk patients after RP set the stage for such investigations. A retrospective analysis of patients with regional lymph node-positive disease found that survival rates were improved in patients who underwent orchiectomy plus RP compared with those who underwent RP alone [40], although a second study showed contradictory results [41]. These findings indicated the need for prospective trials of hormonal therapy after RP in high-risk patients. In one trial, 100 patients were randomly assigned to receive either immediate hormone therapy or observation [42]. In 98 evaluable patients, assessed at a median follow-up of 7.1 years, early hormone therapy showed highly significant advantages, as shown by significantly increased cancer-specific, progression-free, and overall survival rates. Nevertheless, the inability of the study to reach its accrual goals and a lower than expected survival rate in the observation arm have raised concerns regarding whether hormone therapy should be a standard of care [43,44].

The apparent survival advantage observed in patients treated with early and long-duration hormone therapy is reminiscent of the survival advantages observed in patients treated with EBRT plus hormone therapy [45]. Patients with lymph node-positive disease are best managed with adjuvant hormonal therapy. Messing et al demonstrated an improvement in biochemical recurrence-free survival (hazard ratio [HR]: 3.42, 95% CI: 1.96-5.98), cancer-specific survival (HR: 4.09, 95% CI: 1.76-9.49), and overall survival (HR: 1.84, 95% CI: 1.01-3.35) with immediate hormonal therapy after RP compared with therapy at the time of metastasis [46]. Early adjuvant therapy based on improved risk assessments, both in patients with positive margins and those with positive lymph nodes, has been found to improve cure rates in patients in greatest need of cure.

5. Multi-modality therapy: radical prostatectomy, radiation therapy, hormonal therapy, and chemotherapy
Although EBRT with ADT for 2 to 3 years is recommended for patients with high-risk prostate cancer in the 2010 NCCN guidelines, the optimal treatment for these patients has not yet been defined. We need more refined randomized studies of RP with neoadjuvant or adjuvant ADT and/or RT. We are also lacking information on chemotherapy in the neo-adjuvant or adjuvant setting. RP, however, seems to be one of the most important modes of treatment in multi-modal therapy, maximizing survival in patients with locally advanced prostate cancer.

CONCLUSIONS
We believe in the value of aggressive surgical therapy for men with high-risk prostate cancer for the following reasons. Compared with observation alone, RP monotherapy may provide a long-term cancer-specific survival advantage, similar to that of EBRT. RP is the only method currently available for accurate pathological staging, resulting in more accurate risk stratification and guiding the use of multi-modality therapy. Even in patients who fail surgery, RP allows the achievement of durable local control. More accurate stratification of the individual patient’s risk for progression and likelihood of response to treatment is required. In addition, it is necessary to individualize the timing and type of adjuvant therapy.

Conflicts of Interest
The authors have nothing to disclose.
