(Dated: May 12, 2020)

Two of the dominant channels to produce merging stellar-mass black-hole binaries are believed to be the isolated evolution of binary stars in the field and dynamical formation in star clusters. The first black-hole binary event from the third LIGO/Virgo observing run (GW190412) is unusual in that it has unequal masses, nonzero effective spin, and nonzero primary spin at 90% confidence interval. We show that this event should be exceedingly rare in the context of both the field and cluster formation scenarios. Interpreting GW190412 as a remnant of a previous black-hole merger provides a promising route to explain its features. If GW190412 indeed formed hierarchically, we show that the region of the parameter space which is best motivated from an astrophysical standpoint (low natal spins and light clusters) cannot accommodate the observation. We analyze public GW190412 LIGO/Virgo data with a Bayesian prior where the more massive black hole resulted from a previous merger, and find that this scenario is equally supported by the data. If the heavier component of GW190412 is indeed a merger remnant, then its spin magnitude is $q_{\chi} \sim 0.5$, higher than the value previously reported by the LIGO/Virgo collaboration.

Introduction. The first observation of a merging black-hole (BH) binary reported from LIGO/Virgo’s [1, 2] third observing run (O3), GW190412, is unusual in many ways [3].

A BH binary is characterized by component masses $m_1$ and $m_2$, and spins with dimensionless magnitudes $\chi_1$ and $\chi_2$. The masses are conveniently combined into chirp mass $M_c = (m_1 m_2)^{3/5}/(m_1 + m_2)^{1/5}$ and mass ratio $q = m_2/m_1 \leq 1$. The LIGO/Virgo collaboration reports spin constraints in terms of the effective spin $\chi_{\text{eff}} = (\chi_1 \cos \theta_1 + q \chi_2 \cos \theta_2)/(1 + q)$ [4] and of the precession parameter $\chi_p = \max[\chi_{1 \sin \theta_1}, \chi_2 \sin \theta_2 q(4q + 3)/(4 + 3q)]$ [5], where $\theta_{1,2}$ are the angles between the individual BH spins and the orbital angular momentum of the binary.

The events detected in the previous LIGO/Virgo observing runs (O1 and O2) had nearly equal masses ($q \approx 1$), aligned spins components resulting in $\chi_{\text{eff}} \approx 0$, and did not allow for meaningful measurements of $\chi_p$ [6, 7] (but see [8, 9]). The event GW190412 [3] is unusual because it has unequal masses ($q = 0.28^{+0.13}_{-0.07}$), the effective spin $\chi_{\text{eff}} = 0.25^{+0.09}_{-0.11}$ is nonzero, and there is marginal evidence for spin precession ($\chi_p = 0.30^{+0.19}_{-0.15}$). The source-frame chirp mass is $M_c = 13.27^{+0.40}_{-0.32}$. Here we quote medians and 90% symmetric confidence intervals obtained by combining samples from different waveform families, although there are some systematic differences between the models [3].

Based on the population of BHs detected during O1 and O2, Ref. [10] predicted that 99% of the events should have $q \gtrsim 0.5$, and GW190412 is well outside that region. The unusual character of this event is also reflected in the population fit reported in Ref. [3], where the inferred slope of the mass-ratio spectral index is found to change dramatically (from $\beta \sim 7$ to $\beta \sim 0$) when GW190412 is included in the population. However, this conclusion is questionable: GW190412 was chosen from $\sim 50$ O3 triggers [11] and analyzed with priority precisely because of its unusual properties. Therefore, combining it with the previous limited O1/O2 sample of only 10 events can produce statistical biases.

Astrophysical models of core-envelope interactions in massive stars predict that most BHs are born very slowly rotating ($\chi \sim 0.01$) [12]. Ref. [13] found that BH effective spins from O1 and O2 are indeed distributed around zero with a dispersion $\lesssim 0.1$, and this can have important implications in terms of population inference [14, 15]. With a measured primary spin $\chi_1 \sim 0.43$ [3], GW190412 challenges previous predictions. Indeed, its unusual properties have already sparked numerous interpretations in the astrophysics community, ranging from isolated binaries with tidally spun-up secondaries [16, 17] to dynamical assembly in young star clusters [18], gas-assisted migration in AGN disks [19], quadruple stars [20], and super star cluster [21].

Our main goal is to investigate whether one of the components of GW190412 can be interpreted as the remnant of a previous BH merger. Remnant BHs left behind following mergers present a characteristic spin distribution peaked at $\chi \sim 0.7$ [22–24], thus providing a natural way to reconcile the measured value of $\chi_{\text{eff}}$ with small natal spins. Because remnants are, on average, more massive than BHs originating from the collapse of stars, this might also explain the low value of $q$. However, linear momentum dissipation during the late inspiral and merger impacts
a recoil to the BH remnant. A hierarchical merger interpretation is viable only in an environment which (i) allows for frequent dynamical interactions, such that BH remnants can merge again; but at the same time (ii) prevents the ejection of merger remnants due to gravitational recoils [25]. Point (i) excludes isolated binary formation, while point (ii) excludes light dynamical environments, such as globular clusters and young star clusters: these have escape speeds \( \lesssim 50 \text{ km/s} \) [26, 27], while typical gravitational recoils are \( O(100) \text{ km/s} \) [28–31]. Environments with larger escape speeds, like AGN disks [32–34] and/or nuclear star clusters [35], would then be more promising hosts.

**Isolated or hierarchical origin?** We first investigate the likelihood of forming GW190412 in either a hierarchical scenario or from isolated binaries in galactic fields.

To estimate the probability of forming GW190412 in the latter case, we make use of publicly available population-synthesis distributions from Refs. [36, 37] obtained with the StarTrack [38] and PRECESSION [39] codes. These are existing simulations realized with the setup of Ref. [40], which have not been revisited or fine-tuned in any way to reproduce GW190412. In particular we consider seven models, where supernova kicks are extracted from a Maxwellian distribution with one-dimensional dispersion \( \sigma \) between 0 (implying that all BHs have strong fallback at formation) and 265 km/s (as estimated using proper-motion measurement of galactic pulsars [41]). Spins are added to the population-synthesis simulations in post-processing. In particular, we use the “uniform” model of Ref. [36], where the component spin magnitudes are distributed uniformly in [0,1]. This is a conservative assumption in this context, given the measured spins of GW190412. We assume the spins to be initially aligned to the angular momentum of the ZAMS binary, and we track the evolution of their orientations due to supernova kicks and tidal interactions (for tides, we use the “time” model [41]). Rates are computed using the standard noise curve of LIGO at design sensitivity [42]. We then filter the catalogs looking for events that match chirp mass and tidal interactions (for tides, we use the “time” model of Ref. [36]). Rates are computed using the standard noise curve of LIGO at design sensitivity [42]. We then filter the catalogs looking for events that match chirp mass and tidal interactions (for tides, we use the “time” model [41]).

The green curve in Fig. 1 shows, as a function of \( \sigma \), the fraction of the detection rate compatible with binaries similar to GW190412 and the total detection rate \( r \) predicted by each model. Blue and orange curves show results from the hierarchical formation model of Ref. [25] as a function of the escape speed of the environment \( v_{\text{esc}} \). The blue curve (“selective”) assumes a population calibrated to the O1+O2 fit with the addition of second-generation mergers. The orange curve (“random”) assumes that all BHs in the environment pair with equal probability. Green circles are computed from existing population-synthesis simulations of isolated binary stars [36] (an additional datapoint at \( \sigma = 0 \) and \( r_{GW190412} = 1 \) is not shown). In this case, rates are shown as a function of the strength \( \sigma \) of the kicks imparted to BHs at birth. In all cases, thin lines connect results from the simulations, while the thicker line is a log-linear (constant) fit to the case of hierarchical (field) binaries.

FIG. 1. Fraction of the detection rate \( r_{GW190412} \) compatible with binaries similar to GW190412 and the total detection rate \( r \) predicted by each model. Blue and orange curves show results from the hierarchical formation model of Ref. [25] as a function of the escape speed of the environment \( v_{\text{esc}} \). The blue curve (“selective”) assumes a population calibrated to the O1+O2 fit with the addition of second-generation mergers. The orange curve (“random”) assumes that all BHs in the environment pair with equal probability. Green circles are computed from existing population-synthesis simulations of isolated binary stars [36] (an additional datapoint at \( \sigma = 0 \) and \( r_{GW190412} = 1 \) is not shown). In this case, rates are shown as a function of the strength \( \sigma \) of the kicks imparted to BHs at birth. In all cases, thin lines connect results from the simulations, while the thicker line is a log-linear (constant) fit to the case of hierarchical (field) binaries.
these relative rates by a factor of a few, with lower (larger) $v_{\text{esc}}$ corresponding to more (fewer) second-generation events and higher (lower) rates for events like GW190412. Even allowing for second-generation mergers and moderate natal spins, the new event is an extremely unusual draw from the O1+O2 population.

We then repeat the same exercise, but this time we pair the BHs in our sample randomly, i.e. we set $\alpha = \beta = 0$ (solid orange curve in Fig. 1). In this case, the fraction of detectable sources compatible with GW190412 is $\sim 10^{-3}$. This is three orders of magnitude larger than the equivalent dynamical models with “selective” pairing, and one order of magnitude larger than the fraction of events compatible with GW190412 for field binaries.

An important ingredient missing in Fig. 1 is the mixing fraction between the different formation channels. In other words, we compute the fraction of the rate compatible with GW190412 within each model, thus implicitly assuming that those scenarios are all equally probable. Without further assumptions, our analysis does not predict whether the isolated or dynamical formation channels are more likely to have formed GW190412. Our main message here is that both models struggle to reproduce the event: under all of our assumptions, GW190412 appears to be extremely unusual, considering that the public O3 trigger list contains only $\sim 50$ entries [11].

Constraints on the environment. Let us now assume that GW190412 was indeed formed as a second-generation merger. What could we infer about its astrophysical environment?

Making use again of the hierarchical formation model of Ref. [25] with a “random” pairing prescription ($\alpha = \beta = 0$), Fig. 2 illustrates the likelihood of a given environment to be the birthplace of GW190412. We vary the escape speed $v_{\text{esc}}$ and the largest natal spin $\chi_{\text{max}}$ (i.e., first-generation BH spin magnitudes are extracted from a uniform distribution between 0 and $\chi_{\text{max}}$). As before, we select the mergers with observed properties within the 90% confidence intervals of GW190412. The parameters of binaries that survive these cuts are, by construction, all very similar to each other, so their detection rate will also be approximately the same. Therefore the detector sensitivity and antenna patterns only enter the overall rate normalization, which is not captured in Fig. 2.

The left panel of Fig. 2 shows the entire population compatible with GW190412. The region with $\chi_{\text{max}} \lesssim 0.3$ and $v_{\text{esc}} \lesssim 150 \text{ km/s}$ is disfavored, while values of $\chi_{\text{max}} \sim 0.6$ and $v_{\text{esc}} \gtrsim 300 \text{ km/s}$ are preferred. This follows from two complementary constraints:

- If one insists to explain GW190412 as a first-generation BH, then natal spins must allow for the measured value of $\chi_{\text{eff}} \sim 0.25$. The middle panel of Fig. 2 shows the $1g+1g$ subset of the population of compatible binaries and it illustrates that, as expected, it is highly improbable to form GW190412 if $\chi_{\text{max}} \lesssim 0.3$.

- BH remnants can merge again only if their gravitational recoil speed is smaller than $v_{\text{esc}}$. The right panel of Fig. 2 shows the subset of events where one of the two binary members originated from a previous merger (1g+2g). One of the components of GW190412 could be of second generation only in an environment with $v_{\text{esc}} \gtrsim 150 \text{ km/s}$.

The threshold value $v_{\text{esc}} \gtrsim 150 \text{ km/s}$ is set by the physics of gravitational recoils. In the $\chi_{\text{max}} \to 0$ limit, all first-generation BHs are nonspinning and their recoils
TABLE I. Medians and 90% symmetric confidence intervals for GW190412 using both the standard prior (1g+1g) and an alternative prior where the primary component is assumed to come from a previous BH merger (1g+2g). Masses are reported in the source frame.

![FIG. 3. Marginalized prior (dashed) and posterior (solid) distributions of the spin magnitudes $\chi_1$ of the primary BH (top panel) and $\chi_2$ of the secondary BH (bottom panel), as obtained with first-generation (blue) and second-generation (red) priors.](image)

A second-generation prior. We now wish to verify whether LIGO/Virgo data for GW190412 support a model where one of the two binary components is the result of a previous merger (1g+2g). We proceed by enforcing Bayesian priors tuned to plausible mass and spin distributions of second-generation mergers (see Refs. [46, 47] for complementary approaches applied to GW170729). We use the LALINFE inference source-characterization algorithm [48] and public gravitational-wave strain data [49, 50].

We start with a “first-generation prior” consistent with the one used in Ref. [3]: detector-frame component masses are distributed uniformly in [3, 50] $M_\odot$, spin magnitudes are distributed uniformly in [0, 0.99], spin directions, orbital orientation and sky position are assumed to be isotropic, the luminosity distance is distributed uniformly in comoving volume in [1, 1200] Mpc, the phase at coalescence is distributed uniformly in [0, 2$\pi$], and the arrival time is distributed uniformly in $t_a \pm 0.1$ s, where $t_a$ is the trigger time recorded by the search algorithm [11].

We repeatedly draw pairs of random samples from this first-generation prior. Each pair is used to create a remnant BH with mass and spin estimated from the numerical-relativity fitting formulae of Refs. [51, 52], as implemented in Ref. [39]. The resulting joint distribution constitutes our two-dimensional prior for the mass and spin magnitude of second-generation BHs. We did not try to approximate our second-generation prior analytically, but rather augmented LALINFE to use a numerical interpolant obtained from $5 \times 10^5$ previously stored evaluations.

Next we analyze the data assuming that mass and spin magnitude of the more massive (primary) BH are extracted from the second-generation prior, whereas all other parameters (including the mass and spin magnitude of the secondary) are sampled from the first-generation prior described above. We use the IMRPhenomPv2 waveform model [53] and the publicly released estimates for the power spectral density [50]. We do not marginalize over instrument calibration errors, but this does not significantly affect the inference on intrinsic parameters like masses and spins [54, 55]. We also perform a control run using the first-generation prior for both compact objects, and verify that it mimics the results of Ref. [3].

Medians and 90% symmetric confidence intervals of the intrinsic parameters obtained with both sets of assumptions are listed in Table I. Figure 3 shows the one-dimensional marginalized priors and posteriors for the spin magnitudes.

The main parameters affected by the second-generation prior are the primary spin $\chi_1$ and the precession combination $X_p$ (for $q \ll 1$ one has $\chi_1 \simeq \sqrt{\chi_{\text{eff}}^2 + X_p^2}$). Whereas the first-generation prior for $\chi_1$ was uniform, the second-generation prior peaks at $\chi_1 \sim 0.7$. This moves the posterior towards higher values relative to the first-generation analysis. Conversely, the spin of the secondary (which had a mild preference for large values in the first-generation analysis) is mostly flat using a second-generation prior.

are bounded by $v_k \lesssim 175$ km/s [44]. Therefore, ejections of second-generation BHs can only take place in environments with escape speed below this critical value. The same trend remains valid in the more general scenario where first-generation spins are nonzero: although much larger kicks are possible in this case, they are rare, and the vast majority of the BHs are imparted recoils of $O(100 \text{ km/s})$ [28–31].

Together, these two constraints exclude the region of the parameter space that is perhaps better motivated astrophysically. If natal spins are as low as $\sim 0.01$ [12], it is highly unlikely to form GW190412 in low-escape-speed environments like globular clusters [45].
All together, this results in $\chi_\text{p}$ peaking at larger values in the second-generation analysis, although part of that offset is driven by the prior. The second-generation $\chi_{\text{eff}} (q)$ posteriors peak at slightly higher (lower) values, reflecting the anticorrelation between these two parameters [56]. The chirp mass posterior is unaffected.

When analyzing data with new priors, especially if narrower, it is important to calculate the Bayes factors $B$ to check whether the new priors are disfavored by the data [57, 58]. We report $\ln B_{1g+1g} = 1.0$. While this implies that no strong conclusions can be drawn, it also suggests that the data does not significantly penalize our narrower second-generation prior. This is far from obvious, as the second-generation prior excludes regions in the parameter space where the first-generation posterior had support.

Motivated by tidal spin-up in isolated binaries, Ref. [16] reweighed the public GW190412 posterior samples in favor of a prior where $\chi_1 = 0$ and only the secondary BH is spinning. This is very different from our assumptions, where the primary is a rapidly rotating remnant.

To keep the computational cost reasonable, we used a waveform model that does not include higher-order modes, which however are detectable in GW190412 [3]. We expect our key results, and in particular the absence of significant evidence in favor or against the second-generation model, to be unaffected by this choice, because higher harmonics mostly affect the estimation of extrinsic parameters of GW190412, such as the luminosity distance and orbital orientation of the binary.

Conclusions. The detection of GW190412 challenged previous predictions. BH binaries with large spins and unequal masses cannot be easily accommodated in any of the major formation channels. Interpreting one component of GW190412 as a remnant of a previous BH merger can reconcile the observation with small spins at birth while explaining the low value of its mass ratio. However, it also requires a dynamical environment with escape speed $\gtrsim 150 \text{ km/s}$, thus excluding prominent hosts like globular and young star clusters. Analyzing GW190412 using a Bayesian prior motivated by second-generation mergers returns Bayes factors of order unity, implying that this assumption is equally supported by the data compared to scenarios where both BHs originate from stellar collapse.
