(Dated: November 5, 2018)

We report high pressure Raman experiments of Black phosphorus (BP) up to 24 GPa. The line widths of first order Raman modes $A_{2g}$, $B_{2g}$ and $A_{2g}$ of the orthorhombic phase show a minimum at 1.1 GPa. Our first-principles density functional analysis reveals that this is associated with the anomalies in electron-phonon coupling at the semiconductor to topological insulator transition through inversion of valence and conduction bands marking a change from trivial to nontrivial electronic topology. The frequencies of $A_{2g}$ and $A_{2g}$ modes become anomalous in the rhombohedral phase at 7.4 GPa, and new modes appearing in the rhombohedral phase show anomalous softening with pressure. This is shown to originate from unusual structural evolution of black phosphorus with pressure, based on first-principles theoretical analysis.

I. INTRODUCTION

The Black phosphorus (BP) is the most stable form among the many allotropic modifications of phosphorus at room temperature and ambient pressure. It is an elemental semiconductor with direct band gap of $\sim$0.3 eV. Recently there is revival of interest in BP from the prospective of a layered material which allows us to study the exciting properties of a mono and few layers of BP\textsuperscript{1}. It is an isoelectronic semiconductor with direct band gap of transition metal dichalcogenide (1.5-2.5 eV)\textsuperscript{4,8} and relatively large band gap of transition metal dichalcogenide (1.5-2.5 eV)\textsuperscript{12,13} and makes it ideal for infrared optoelectronic application. Another interesting feature of BP is its anisotropic atomic structure. At ambient pressure, BP packs into orthorhombic lattice with a puckered honeycomb structure as shown in Fig. 1. Each phosphorus atom is bonded with two in-plane and one out of plane neighboring atoms. The puckered layers are bound together by weak van der Waals interactions. Due to this anisotropic atomic structure, the effective masses of carriers in BP along armchair (ac) are lightest and that along the layer stacking (z) are lighter than that along the zigzag (zz)\textsuperscript{2}. Recent upsurge of interest in layered BP has arisen due to this unique puckered 2D honeycomb lattice in each phosphorus layer, giving anisotropic electronic\textsuperscript{3}, optical\textsuperscript{4,14} and vibrational properties\textsuperscript{4}.

Further, the direct band gap ($\sim$ 0.3 eV) of BP arises from the out-of-plane p$_z$-like orbitals of phosphorus and hence can be strongly modulated by pressure or c-axis strain. Not surprisingly, the effect of pressure was studied on crystal structure and electronic properties in the early work\textsuperscript{16,22}. It has anisotropic compressibility: lattice parameters a and c decrease more in comparison with the lattice parameter b with increasing pressure. At room temperature, the ambient pressure orthorhombic structure transforms to the rhombohedral structure at $P_c$ $\sim$4.7 GPa and then to the simple cubic structure (sc) at $P_{c_3}$ $\sim$ 11 GPa\textsuperscript{22}. These transition pressures are slightly higher if sample is cooled to liquid helium temperature first and then pressure is increased. The sc phase transforms to a simple hexagonal (sh) phase at higher pressure 137 GPa via an intermediate phase\textsuperscript{23}. Recently, Alabama et. al\textsuperscript{24} investigated the crystal structure of black phosphorus up to 280 GPa at room temperature using x-ray-diffraction experiment and found that sh phase goes to the bcc structure at 262 GPa. The sc phase exhibits superconductivity at 4.7 K\textsuperscript{25,26}. The superconducting temperature is slightly pressure dependent and increases with increasing pressure. The superconducting state remains for several hours even if the pressure is removed. BP shows superconductivity with high transition temperature (10K) when it is cooled to 4K first and then pressure is applied. These experiments clearly establish that high pressure can be used to tune the material characteristic of BP significantly.

The electrical conductivity of black P is also very sensitive to pressure\textsuperscript{27,29}. Two anomalies have been reported at 1.7 and 4.2 GPa, the latter coinciding with the structural phase transition from orthorhombic to rhombohedral structure. The earlier work\textsuperscript{28} reported that the band gap decreased linearly with a pressure coefficient of $\sim$ 0.17 eV/ GPa, closing at $P_{c_3}$ $\sim$ 1.5 GPa. Recent magneto-resistance studies\textsuperscript{30} have termed this transition as electronic topological transition (ETT) from semiconductor to 3D Dirac semi-metal due to band crossover near the Z-point in the Brillouin zone with linear dispersion. Interestingly, a colossal magneto-resistance of $\sim$ 80,000 is seen at 2GPa at a field of 9T, similar to 2D Weyl semi-metals like WTe$_2$, making BP as an elemental semi-metal with increased electronic structure.

Pressure and strain have been used to change the rela-
tive strength of spin-orbit coupling and induce electronic topological transition (ETT) in materials like Sb$_2$Se$_3$, b-As$_2$Te$_3$, BiTeI. Recently, Gong et al. theoretically reported a pressure-induced Lifshitz transition at a pressure of 1.2 GPa where black phosphorus undergoes a semiconductor to three-dimensional Dirac semimetal transition. By using first-principles density functional theoretical calculations within GGA and mBJ exchange-correlation functional, Gong et al. showed that the band inversion occurs at the Z point at 1.2 GPa and robust three-dimensional Dirac points appear away from the Z point. Recently a theoretical study by Manjanath et al. reported a reversible semiconductor to metal transition in bilayer phosphorene by applying normal compressive strain. In another work, Xiang et al. reported colossal positive magneto-resistance in black phosphorus for P $\geq$ 1.2 GPa and observed a non-trivial $\pi$ Berry phase from the Shubnikov-de Haas oscillation measurement. These observed changes in black phosphorus at pressure of 1.2 GPa were attributed to an electronic Lifshitz transition.

The role of lattice in pressure-induced electronic topological transition has been evident in softening of an acoustic phonon mode at 1.54 GPa in an earlier inelastic neutron scattering experiment, where anomalous compressibility and softening of longitudinal ultrasonic wave propagating along c-axis hint the relevance of electron-phonon interaction to pressure induced transitions. High pressure Raman spectroscopy, a sensitive probe of lattice distortion under pressure, has been used in BP up to 13 GPa pressure, displaying changes in the pressure coefficients of Raman frequencies of a few modes as well as anomalous compressibility. (i) The new modes labeled N1, N2 and N3 observed in the rhombohedral phase have been quantitatively analyzed theoretically for the first time, capturing their anomalous softening. The modes N1, N2 and N3 have been assigned to $E'_2$, $A_g$ and $E'_2$ modes respectively. The modes N1 and N2 in the sc phase are assigned as X and M point acoustic modes, respectively.

II. EXPERIMENTAL DETAILS

Raman measurements were carried out at room temperature in back scattering configuration with micro-optical system equipped with Horiba 800 spectrometer, Peltier-cooled charge controlled detector and 532 nm diode laser. Pressure was generated using a diamond anvil cell (DAC) using 4:1 methanol: ethanol pressure transmitting medium. A thin platelet of dimension $\sim$ 100$\mu$m cleaved from single crystals of BP, (from M/S Smart Elements) was placed into a stainless steel gasket with sample chamber hole of $\sim$ 200$\mu$m inserted between the diamonds along with a ruby chip for pressure calibration. Laser power ($< 5$mW) was kept low enough to avoid damage to the sample.

III. COMPUTATIONAL DETAILS

Our first-principles calculations are based on density functional theory (DFT) as implemented in the Quantum ESPRESSO package, with the interaction between ionic core and valence electrons modeled with norm-conserving pseudopotentials. The exchange-correlation energy of electrons is treated within a generalized gradient approximation (GGA) with a functional form parameterized by Perdew, Burke and Ernzerhof. We use an energy cutoff of 55 Ry to truncate the plane wave basis used in representing Kohn-Sham wave functions, and energy cutoff of 220 Ry for the basis set to represent charge density. Structures are relaxed to minimize energy till the magnitude of Hellman-Feynman force on each atom is less than 0.03 eV/Å. We include van der Waals (vdW) interaction with the parametrization given in Grimme scheme. In self-consistent Kohn-Sham (KS) calculations of configurations of bulk black phosphorous with orthorhombic and rhombohedral unit cell, the Brillouin zone (BZ) integrations were sampled with a uniform mesh of 18x16x16 and 16x16x16 k-points respectively, and 32x32x32 mesh of k-points was used in calculation of electron-phonon coupling of both the structural forms. Phonon spectra and dynamical matrices at $\Gamma$-point ($q=(0,0,0)$) as a function of lattice constant (or pressure) were determined using density functional linear response as implemented in Quantum ESPRESSO (QE), which employs the Green’s function method to avoid explicit calculations of unoccupied Kohn-Sham states. Since DFT typically underestimates the electronic bandgap, we have used HSE functional to estimate the gaps accurately, with the mixing parameter of 0.25 and reciprocal
space integration sampled on a 4x4x4 mesh of k-points. We have fully relaxed the orthorhombic structure of BP with HSE calculations maintaining the experimental c/a ratio. We find that the error in resulting cell volume (relative to experiments) is negligibly zero (Fig. 2 (a)). Fitting a quadratic function to energy vs. volume curve, we used $\frac{\partial E}{\partial v}$ to estimate pressures within HSE calculations. We determine electronic bandgap at Z-point as a function of volume, and used the point of minimum bandgap to estimate the transition pressure within HSE calculations (Fig. 2 (b)).

$Z_2$ topological invariants can be defined using the notion of time reversal polarization $I^{T}_{\nu}$ derived in terms of hybrid Wannier charge centers (WCCs)$^{45}$. In a time-reversal invariant system, electronic bands always come derived in terms of hybrid Wannier charge centers (WCCs) $^{45}$. In a time-reversal invariant system, electronic bands always come invariant under time reversal symmetry, where $T$ represents the period of a full cyclic adiabatic evolution. In the Brillouin zone of a periodic crystal $T$ is equivalent to a reciprocal lattice vector which defines the periodicity in the reciprocal space. The topological invariant of a plane is non-zero if the WCCs switch pairs under an adiabatic evolution in the half-cycle, which can be easily tracked by seeing evolution of the mid-point of the largest gap (as marked by blur rhombus in Fig. 6) between two adjacent WCCs with $t \in [0, \pi/2]$ in the half-cycle. In this case, the rhombuses exhibits abrupt jumps in their half-cyclic evolution and cross odd number of WCCs $^{45}$. We have calculated the strong topological index ($i_0$) by taking the sum (modulo 2) of the topological invariants calculated at $k_x=0$ and $k_z=0.5$ planes in the Brillouin zone of black phosphorous using ZZPack code $^{45}$. At each of these planes, WCC, calculated along $k_x$ direction, evolve along the $k_y$ direction (parameterized with time, $t$).

IV. RESULTS AND DISCUSSION

A. Experimental Results

The unit cell of BP contains 4 atoms which gives 12 normal modes. According to factor group analysis, at ambient pressure the Brillouin zone center point phonon modes are $2A_g + B_{1g} + B_{2g} + 2B_{3g} + A_u + 2B_{1u} + 2B_{2u} + B_{3u}$: out of which $2A_g$, $B_{1g}$, $B_{2g}$ and $2B_{3g}$ are Raman active. Experimentally three Raman modes $A^1_g$, $B_{2g}$ and $A^2_g$ were observed at 360, 438 and 460 cm$^{-1}$ respectively as shown in lower panel of Fig. 5. The other two previously reported $^2$ Raman modes $B_{1g}$ (192 cm$^{-1}$) and $B_{3g}$ (227 cm$^{-1}$) are very weak and difficult to separate from the background. The phosphorus atoms vibrate along the out of plane ($z$) for the $A^1_g$ (360 cm$^{-1}$) mode, along armchair ($y$) for the $B_{2g}$ (438 cm$^{-1}$) mode and zig zag ($x$) directions for the $A^2_g$ (460 cm$^{-1}$) mode. Fig. 6 shows the pressure evolution of the Raman spectra of BP at a few representative pressures. The Lorentzian line shapes are used to fit the Raman spectra at different pressures to obtain phonon frequencies and full width at half maximum (FWHM). From Fig. 6 it can be seen that the intensities of $A^1_g$, $B_{2g}$ and $A^2_g$ Raman modes of the orthorhombic structure decrease gradually with pressure and disappear completely at 11 GPa. Further, two new Raman modes labelled as $N_1$ and $N_2$ at 240 and 300 cm$^{-1}$ respectively, emerged at 4.6 GPa and remain till 24 GPa. Another new mode labelled as $N_3$ at 370 cm$^{-1}$ arises at 7.4 GPa and diminishes at 15.9 GPa. To shed more light on the evolution of modes $N_1$, $N_2$ and $N_3$ with pressure, we examine the frequencies and area of $N_1$, $N_2$ and $N_3$ peaks as a function of pressure (see Fig. 5). It is clear that the intensity of $N_1$ mode increases slowly with increasing pressure till 10 GPa, and rapidly beyond 10 GPa. The intensity of $N_2$ and $N_3$ modes increases with pressure till 13 GPa, and decreases beyond that. The phonon frequencies of $N_1$, $N_2$ and $N_3$ modes soften with pressure.

Fig. 5 shows the pressure dependence of phonon frequencies. The solid blue lines are the linear fit to the experimental data points. The vertical dashed red lines indicate two structural phase transitions from orthorhombic to rhombohedral and from rhombohedral to simple cubic phase. Fig. 5 shows that the frequencies of $A^1_g$, $B_{2g}$ and $A^2_g$ modes show increase with pressure in orthorhombic phase. The slope for the $A^1_g$ ($S=\omega/dP$) is more as compared to that for the $B_{2g}$ and $A^2_g$ modes. Noting that the eigen vectors of the $A^1_g$ mode are perpendicular to the puckered layers, larger pressure derivative of frequency ($S$) signifies that van der Waals bond can be greatly compressed. Fig. 5 also shows that all the three modes of the orthorhombic phase ($A^1_g$, $B_{2g}$ and $A^2_g$) persist even beyond 4.6 GPa. This can be due to two possibilities (i) that the orthorhombic to rhombohedral transformation is completed only at $\sim$ 11 GPa; (ii) the Raman active modes of the rhombohedral phase are at the frequencies close to the values in the orthorhombic phase. The latter possibility is ruled out as the frequencies of Raman modes in rhombohedral phase (to be discussed latter) are not close to the above three modes. In rhombohedral phase at 7.4 GPa, $A^2_g$ and $B_{2g}$ modes soften anomalously (the effect is more for $B_{2g}$ mode). Further Fig. 5 shows that the Raman modes $N_1$, $N_2$ and $N_3$ show anomalous softening with pressure in rhombohedral as well as in simple cubic phase. It is clear from Fig. 5 that the slope $S$ for the $N_3$ mode is more than $N_1$ and $N_2$ modes. Fig. 6 (a) shows the effect of pressure on FWHM of the Raman modes. The range from 0 to 4 GPa has been magnified in Fig. 6 (b). The solid blue lines are the linear fit. It
is clear from Fig. 3(b) that the FWHM of all the three Raman modes show a minimum at 1.1 GPa which coincide with the ETT transition pressure. Another thing to note is that the line width of N1, N2 and N3 modes are very large. We don’t fully understand the origin of the large linewidths of these modes in the rhombohedral phase. One possible origin could be the high disorder in the rhombohedral phase. We now present our theoretical calculations to understand the anomalies in phonon spectra with pressure observed in the experiments.

B. Theoretical calculations

1. Low Pressure Transition

BP is a semiconductor with a gap of 0.40 eV at Z-point (0.0, 0.0, 0.5) as estimated with HSE functional (Fig. 4(a)), which is in good agreement with the experiment ($E_g = 0.35$ eV). We note that there is no band gap in the structure at 0 GPa calculated with GGA functional based theory (Fig. 4(b)). Raman experiments (Fig. 4(b)) showed non-monotonic dependence of FWHM of $A_g^1$, $B_{2g}$ and $A_g^2$ modes on pressure, displaying a minimum at 1.1 GPa. Since the anomalous change in FWHM can be an indicator of electronic topological transition (ETT), and given the experimental observations of Xiang et al. and theoretical study of Gong et al., we first studied electronic structure of black phosphorus as a function of hydrostatic pressure using highly accurate HSE calculations. Our calculations show that the band inversion occurs at Z point at $P_c$ ($\sim 1.2$ GPa), which is in good agreement with the experimental observations of Xiang et al., and also close to the pressure of observed Raman anomalies ($P_c \sim 1.1$ GPa).

Although earlier studies reported pressure induced electronic topological transition (Lifshitz transition) in black phosphorus following band inversion near $P = 1.2$ GPa, the nature of electronic topology has not been clearly elucidated. To investigate the electronic topology of black phosphorus, we determined the $Z_2$ topological invariant ($\nu_0$) as a function of pressure (Fig. 5). The evolution of hybrid Wannier charge centers (WCCs) along $k_y$-direction is marked by circle while their largest gap function is marked by blue rhombus for $k_z = 0$ plane and $k_z = 0.5$ plane. It is clear from Fig. 5(a),(b) that for $P < 1.2$ GPa both $k_z = 0$ and $k_z = 0.5$ planes are topologically trivial as $Z_2$ invariants for both the planes are zero, and hence strong topological index $\nu_0 = 0$. However, at $P > 1.2$ GPa (Fig. 5(c),(d)), $Z_2$ invariant for $k_z = 0$ plane is 1, as evident from the discontinuous jump of the gap function along $k_y$, whereas $Z_2$ invariant is zero for $k_z = 0.5$ plane, and hence the strong topological index $\nu_0$ of the state at this pressure is 1. Thus we find that $\nu_0 = 0$ for $P < 1.2$ GPa, whereas $\nu_0 = 1$ for $P > 1.2$ GPa signifying $Z_2$ topological insulating nature of black phosphorus above 1.2 GPa. Thus, the minimum in FWHM of Raman active modes at ($P_c$) is correlated with the pressure induced electronic topological phase transition. The observation of non-trivial $\pi$ Berry phase and colossal magneto-resistance for $P > 1.2$ GPa in experiment are also consistent with our finding that the BP becomes topologically non-trivial for $P > 1.2$ GPa. The discrepancy between our calculated transition pressure (1.2 GPa) and previously reported ones (0.6 GPa) falls within the typical errors of DFT calculations.

Calculations of phonon frequencies and electron-phonon coupling are not straightforward with the HSE functionals because (i) DFT-LR (DFT linear response) implementation with HSE functional is not available presently and (ii) frozen phonon method with fine mesh
FIG. 2. Change in energy (a) and bandgap at Z-point of Brillouin zone (b) with volume obtained from calculations with GGA and HSE functionals. Red and blue dashed lines mark the equilibrium structure of BP in orthorhombic phase. Note that green dashed line highlights the volume at which bandgap of HSE-relaxed structure exhibits a minimum, making the electronic topological transition.

of k-points make HSE calculation very computationally intensive. Thus we have used GGA functional in understanding the observed phonon anomalies. We correct the pressures estimated in GGA calculations with a shift of 2.7 GPa, to match the transition pressure estimated with HSE calculations in the orthorhombic phase. Our optimized structural parameters of orthorhombic structure, a, b, c, \(d_1\), \(d_2\), \(\alpha_1\) and \(\alpha_2\) are 4.42 Å, 3.32 Å, 10.46 Å, 2.224 Å, 2.244 Å, 96.34° and 102.09° respectively, in good agreement with the experimental and earlier reported theoretical values. Here \(d_1\) is the bond length of in-plane P atoms, \(d_2\) defines the distance out-of-plane P atoms; \(\alpha_2\) and \(\alpha_1\) are the bond angles between \(d_1\) and \(d_2\), and the two \(d_1\) bonds respectively (see Fig. (b)).

Our calculated frequencies of \(A_{2g}\), \(B_{2g}\) and \(A_1\) modes using GGA functionals are 453 cm\(^{-1}\), 424 cm\(^{-1}\) and 354 cm\(^{-1}\), which agree well with the observed frequencies (460 cm\(^{-1}\), 438 cm\(^{-1}\) and 360 cm\(^{-1}\)) of these modes.

We now examine the minimum in the FWHM (at \(P_{c1}\)) which is related to the electron phonon coupling constant \(\lambda\). The dependence of \(\lambda\) of the three Raman modes on pressure shows a dip at -1.5 GPa. We have gone to negative pressure because GGA calculations show semiconductor to semi-metal transition at \(P_{c1} = -1.5\) GPa. The discrepancy in \(P_{c1}\) using GGA functionals as compared
FIG. 3. Pressure evolution of Raman spectra. The solid lines (red and blue) are the Lorentzian fits to the experimental data (black). N1, N2 and N3 are the new modes.
to experiment (P_{c1} = 1.1 GPa) and HSE functionals (P_{c1} = 1.2 GPa) points to the inadequacy of the GGA functionals in estimation of bandgap and predicting the transition pressure. The corrected transition pressure will be P_{c1}^{corrected} = 1.5 + 2.7 = 1.2 GPa as indicated in Fig. 7(d). This correction is used in the pressure axis in plotting Fig. 8 (c). Further, with increasing pressure, the gap closes in the vicinity of Z-point at P_{c1}^{corrected} = 1.2 GPa (Fig.7(d)). Fig. 8 (c) reveals that the λ does show a shallow minimum at P_{c1}^{corrected} = 1.2 GPa for the A_{1g} and A_{2g} modes, clearly establishing the link between a dip in λ and FWHM with the ETT. We did not see any anomaly in the λ of B_{2g} mode with pressure.

The linewidth of a phonon mode of a crystal exhibiting a strong electron-phonon interaction is largely determined by electron-phonon coupling (EPC). The relation between the EPC (γ_{qv}) and FWHM (γ_{qv}) of a phonon ν at wavevector q is given by the following expression,

\[ \lambda_{qv} = \frac{\gamma_{qv}}{\pi h N(\epsilon_F) \omega_{qv}^2}, \]  

where \( N(\epsilon_F) \) is the density of electronic states at Fermi level. From Eq. (2), it is clear that λ and FWHM are proportional to each other. Since the density of states and electronic bands involved in the matrix elements γ_{qv} change upon band inversion at the ETT, there is thus a causal relationship with anomaly in FWHM. Hence, we see a minimum in FWHM and λ at a mode at the transition pressure. The anomalous change in observed FWHM may not in general indicate an electronic topological transition (ETT). In the present context, however, a careful analysis of calculated electronic structure of black phosphorous reveals a band inversion across the transition pressure (≈ 1.2 GPa), indicating the occurrence of an ETT. Our calculations of Z_2 invariant across \( P_{c1} \approx 1.2 \) GPa confirm this topological transition from trivial semiconductor to topological semimetallic state. ETT is accompanied by the Lifshitz transition, the electronic structure changes and the charge density of P atoms redistributes, leading to the anomaly of Raman spectra.

2. Anomalies at High Pressure Transitions: Structural Origin

We now address the pressure dependence of phonon frequencies of A_{1g}, A_{2g} and B_{2g} modes of the orthorhombic phase. The calculated frequencies of the orthorhombic phase as a function of pressure (Fig. 11) clearly display that the frequencies of A_{1g} and A_{2g} modes harden up to ≈ 5 GPa. Interestingly, the frequency of B_{2g} and A_{2g} modes show softening at high pressure; resembling with the anomalous pressure dependence of the B_{2g} and A_{2g} modes seen in the experiments between 7 and 9 GPa (Fig. 6). To correlate the softening of the B_{2g} and A_{2g} modes with structural modifications, we examine the pressure dependence of the internal parameters \( d_1, d_2, \alpha_1 \) and \( \alpha_2 \) (see Fig. 1 for description).

Atomic vibrations of the A_{1g} mode (Fig. 10) involve stretching of the \( d_2 \) bond. From the variation in \( d_2 \) bond with pressure (Fig. 11(a)), we find that \( d_2 \) decreases monotonically with pressure and the \( \Delta d_2 \) is ≈ 0.04 Å up to 14.7 GPa. As a result, A_{1g} hardens with pressure. The atomic vibrations of the B_{2g} mode (Fig. 10) affect bond angle \( \alpha_2 \), which decreases with increasing pressure (Fig. 11(b)), similar to the frequency of B_{2g} mode. Atomic displacements of the A_{2g} mode (Fig. 11) involve stretching of the \( d_1 \) bond. Fig. 11(a) shows that \( d_1 \) decreases with pressure up to 6 GPa, and starts increasing from 7-11 GPa, and subsequently decreases with pressure up to 14.7 GPa. In this case, the change in \( d_1 \) with pressure is much smaller than that in \( d_2 \), which is also reflected in softening of B_{2g} and A_{2g} modes. As a result of variation of \( d_1 \) with pressure, the A_{2g} mode softens with pressure and this softening is less than the softening of the B_{2g} mode. The pressure axes of Fig. 10 and Fig. 11 are corrected with a shift of +2.7 GPa as described in the previous section. Our theoretical calculations reveal that black phosphorous is quite a soft material, with its cell volume at 14.7 GPa being 24% smaller than that at 0 GPa. This large change in volume with pressure is responsible for significant softening of B_{2g} and A_{2g} modes. For such large changes in volume, we expect anharmonic effects to be strong, which are not included in our analysis. This is probably responsible for some discrepancy between theory and experiments. We find that the observed softening of A_{2g} mode (Fig. 11) is not indefinite: A_{2g} mode harden with further increase in pressure beyond 15 GPa, consistent with our experiments.

Orthorhombic phase is a low pressure phase of black phosphorous which is stable only at P < 5 GPa. We presented results of our calculations on orthorhombic phase at P > 5 GPa because experiments are indicative of the presence of mixed phases at higher pressure, as evidenced in the survival of A_{1g}, B_{2g} and A_{2g} modes at high pressures along with the modes N1 (\( E_g \)), N2 (\( A_{1g} \)) and N3.

FIG. 4. Pressure dependence of phonon frequencies and area of N1, N2 and N3 modes.
FIG. 5. Pressure dependence of phonon frequencies. The vertical dashed lines indicate the two structural phase transition pressures. The solid blue lines are the linear fit. The slope $d\omega/dP$ in units of cm$^{-1}$/GPa is given near the lines.

$(E_g)$ of the rhombohedral phase (refer Fig. 5). As the calculations here are on pure and not on mixed phases (orthorhombic and rhombohedral phases together as seen in experiment), interpretation of experimental and theoretical results should be done with care.

The space group of BP in rhombohedral structure (also known as A7 phase after 4.6 GPa) is $R3m$ with primitive cell containing 2 atoms. Group theory gives zone center optical modes as $A_{1g}+E_g+A_{2u}+E_u$, where $A_{1g}$ and $E_g$ are the Raman active modes and $A_{2u}$ and $E_u$ are infrared active modes. We used hexagonal unit cell with 6 atoms (i.e. a supercell) to perform phonon calculations for A7 phase. Some of the zone boundary points of BZ of rhombohedral structure (i.e. the primitive cell) fold onto the $\Gamma$-point of BZ of the hexagonal unit cell, and enable the analysis of Raman active modes and their symmetries. The frequencies of the Raman active modes $E_g^2$, $A_{1g}$ and $E_g^1$ modes are 367 cm$^{-1}$, 336 cm$^{-1}$ and 242 cm$^{-1}$ respectively at 4 GPa. Calculated frequencies of these modes are in good agreement with experimental values (e.g. at 6 GPa, $\omega$ (N1) = 237cm$^{-1}$ (Exp. 237cm$^{-1}$), $\omega$ (N2) = 311 cm$^{-1}$ (Exp. 307 cm$^{-1}$)). We identify the experimentally observed N3 mode as $E_g^2$, N2 mode as $A_{1g}$ mode and N1 mode as $E_g^1$. Symmetry assignment of N2 and N1 modes is consistent with previous report. All the three modes N1, N2 and N3 soften with pressure, in agreement with
FIG. 6. (a) Pressure evolution of FWHM of Raman modes. The vertical dashed lines indicate the two structural phase transition pressures. (b) Magnified plot FWHM in the pressure range 0 to 4 GPa. The vertical dashed line indicates the semiconductor to topological insulator phase transition pressures. The solid blue lines are linear fit. The slope $d\omega/dP$ in units of cm$^{-1}$/GPa is given near the lines. (c) Variation in the calculated electron-phonon coupling of Raman active modes $A_{1g}$, $B_{2g}$, and $A_{2g}$ of BP with pressure in orthorhombic phase calculated using GGA functional. The pressure axis has been corrected as explained in the text. The vertical dashed line indicates the semiconductor to topological insulator phase transition pressures.

V. CONCLUSION

High pressure Raman study of BP up to 24 GPa is reported using diamond anvil cell under hydrostatic conditions. The line width of all the three Raman modes $A_{1g}$, $B_{2g}$, and $A_{2g}$ of the orthorhombic phase decrease with pressure up to 1.1 GPa and then increase, thus showing a minimum at $\sim$ 1.1 GPa corresponding to the transition pressure of ETT. Using first-principles calculations, we find that the low pressure phase transition in BP is a semiconductor to topological insulator transition. Our calculations of the $Z_2$ invariant confirm the change in electronic topology marking a transition from band to topological insulating state. The Raman shift of these modes show normal hardening with pressure in orthorhombic phase. $B_{2g}$ and $A_{2g}$ modes show anomalous softening in rhombohedral phase at 7.4 GPa while $A_{1g}$ mode exhibits normal hardening. These modes disappear completely at 11 GPa in the sc phase. The new modes N1, N2 and N3 arising in rhombohedral phase also show anomalous softening of the frequency with pressure. We uncover the origin of these anomalous softening of Raman modes in the variation of internal structural parameters with pressure, and identify the symmetry of the new modes appearing upon pressure in experiments.

FIG. 7. Electronic structure of BP in orthorhombic phase. (a) Electronic structure of BP at $P = 0$ GPa calculated with HSE functionals. Note that we used Wannier functions to plot band structure with HSE functionals. (b) Comparison of electronic structure near the gap obtained with HSE and PBE functionals at $P = 0$ GPa. BP exhibits a gap of 0.33 eV at Z-point, which is captured correctly with HSE functionals whereas PBE calculations gives no gap. (c) Electronic structure near the gap obtained with HSE functionals at different pressures. (d) Electronic structure of BP calculated with PBE-GGA functional at different pressures. The pressures have been corrected as explained in the text. At $P_{\text{corrected}} = 0.7$ GPa, calculations with PBE functionals show a gap which closes at $P_{\text{corrected}} = 1.2$ GPa. With further increase in pressure, bandgap closes in vicinity of Z-point at $P_{\text{corrected}} = 1.7$ GPa.
FIG. 8. Band inversion during pressure induced electronic topological transition (ETT) in BP. Isosurfaces of charge densities associated with electronic states at valance band maximum (VBM) and conduction band minimum (CBM) at Γ-point (a) before and (b) after the ETT revealing band inversion across this transition.

FIG. 9. Calculation of $Z_2$ topological index ($\nu_0$) before ($P < 1.2$ GPa) and after ($P > 1.2$ GPa) the phase transition. Evolution of hybrid Wannier charge centers (WCCs) along $k_y$-direction (marked by circle) and their largest gap function (blue rhombus) for (a) $k_z=0$ plane and (b) $k_z=0.5$ plane. It is clear that both $k_z=0$ and $k_z=0.5$ planes are topologically trivial as $Z_2$ invariants for both the planes are zero, hence strong topological index $\nu_0=0$. At $P > 1.2$ GPa, $Z_2$ invariant for $k_z=0$ plane is 1, as evident from the discontinuous jump (indicated by red dotted line) of the gap function along $k_y$ (c), whereas $Z_2$ invariant is zero for $k_z=0.5$ plane (d), hence the strong topological index $\nu_0$ at this pressure is 1.
FIG. 10. Change in the calculated frequencies of Raman active modes (a) $A_2^g$, (b) $B_{2g}$ and (c) $A_2^g$ modes of BP in orthorhombic phase with pressure. Insets of (a), (b) and (c) show atomic displacements in these Raman active modes. The pressure axis has been corrected as explained in the text.

FIG. 11. Evolution of bond lengths (a) and bond angles (b) of BP in orthorhombic phase with pressure. The pressure axis has been corrected as explained in the text.

FIG. 12. Changes in the calculated frequencies of Raman active modes of BP, (a) $E_2^g$ (N3), (b) $A_{1g}$ (N2) and (c) $E_1^1$ (N1) modes in rhombohedral phase (right panel shows their atomic displacements) with pressure, (d) N2 and (e) N1 modes with pressure of BP in cubic phase. Note that N1, N2 and N3 are the modes observed in experiments. N2 and N1 modes as shown in figure (d) and (e) correspond to the acoustic modes at X and M-points in the Brillouin Zone of the simple cubic phase.

FIG. 11. Evolution of bond lengths (a) and bond angles (b) of BP in orthorhombic phase with pressure. The pressure axis has been corrected as explained in the text.
