Tilted spin current generated by the collinear antiferromagnet ruthenium dioxide

Arnab Bose\textsuperscript{1,2,7}, Nathaniel J. Schreiber\textsuperscript{3,7}, Rakshit Jain\textsuperscript{1,2,7}, Ding-Fu Shao\textsuperscript{4}, Hari P. Nair\textsuperscript{3}, Jiaxin Sun\textsuperscript{3}, Xiyue S. Zhang\textsuperscript{1}, David A. Muller\textsuperscript{1,5}, Evgeny Y. Tsymbal\textsuperscript{4}, Darrell G. Schlom\textsuperscript{3,5,6} and Daniel C. Ralph\textsuperscript{2,5}

Symmetry plays a central role in determining the polarization of spin currents induced by electric fields. It also influences how these spin currents generate spin-transfer torques in magnetic devices. Here we show that an out-of-plane damping-like torque can be generated in ruthenium dioxide (RuO\textsubscript{2})/permalloy devices when the Néel vector of the collinear antiferromagnet RuO\textsubscript{2} is canted relative to the sample plane. By measuring characteristic changes in all three components of the electric-field-induced torque vector as a function of the angle of the electric field relative to the crystal axes, we find that the RuO\textsubscript{2} generates a spin current with a well-defined tilted spin orientation that is approximately parallel to the Néel vector. A maximum out-of-plane damping-like spin torque efficiency per unit electric field of $7 \pm 1 \times 10^3 \Omega^{-1} \text{m}^{-1}$ is measured at room temperature. The observed angular dependence indicates that this is an antiferromagnetic spin Hall effect with symmetries that are distinct from other mechanisms of spin-current generation reported in antiferromagnetic and ferromagnetic materials.

For magnetic heterostructures in which an in-plane electric field causes a spin-current-generating layer to exert a spin-transfer torque on an adjacent magnetic layer, rotational and reflection symmetries present in the spin-current-generating layers typically restrict the allowed spin polarization of the electric-field-induced spin current to a single axis, in the sample plane and perpendicular to the applied electric field (E). This is unfortunate, because this spin orientation cannot drive efficient anti-damping switching of magnetic devices with perpendicular magnetic anisotropy. One way to avoid this problem is to lower the symmetry of the spin-current-generating material, which makes more general spin orientations possible. This has been demonstrated in materials in which the symmetry is lowered via the crystal structure\textsuperscript{1–4} or ferromagnetic moments\textsuperscript{5–14}. However, the resulting out-of-plane anti-damping torques have not been shown to be strong enough for practical applications. Alternatively, spin currents with out-of-plane spin components emerging from antiferromagnets have been predicted and measured\textsuperscript{15–22}. This is potentially valuable because the spin-current generation in antiferromagnets appears to result primarily from mechanisms—exchange interactions and Berry curvature induced by non-collinear spin order—that could be stronger than the spin–orbit interactions (SOIs) that have been the previous focus of the field.

It was recently proposed that the collinear antiferromagnet ruthenium dioxide (RuO\textsubscript{2}) might produce strong electric-field-induced spin currents with spin orientation approximately aligned along the Néel vector\textsuperscript{23}. This spin generation has been identified\textsuperscript{23} as the property of a general class of collinear antiferromagnets exhibiting momentum-dependent spin splitting\textsuperscript{24,25}. In this mechanism, a spin-split band-structure, caused by inequivalent crystal environments for the two spin sublattices, yields spin currents with spin polarization parallel to the Néel vector. When the Néel vector is appropriately canted, the result can be a vertically flowing spin current with a strong out-of-plane spin component.

In this Article we report measurements of E-induced torques within RuO\textsubscript{2}/permalloy (Py) devices. The full three-dimensional spin-orientation of the E-induced spin is extracted by measuring the E-induced torques as a function of the angles of both the applied magnetic field and the E relative to the crystal axes. We determine that RuO\textsubscript{2} produces an E-induced spin–current polarization aligned approximately (but not exactly) with the Néel vector $\mathbf{N}$, which is in good agreement with the spin-splitter mechanism for RuO\textsubscript{2}. This mechanism is distinct from the recently reported spin Hall effect (SHE) in the collinear antiferromagnet Mn\textsubscript{2}Au (ref. 21). In Mn\textsubscript{2}Au, the spin polarization of the spin current is perpendicular to $\mathbf{N}$, and the out-of-plane anti-damping torque is maximized when E is parallel to $\mathbf{N}$. In the spin-splitter mechanism in RuO\textsubscript{2}, the spin polarization of the spin current is approximately parallel to $\mathbf{N}$, and the out-of-plane spin current requires $\mathbf{N}$ to be canted out of the sample plane.

**SHE in RuO\textsubscript{2}**

RuO\textsubscript{2} is a conductive rutile oxide belonging to space group $P4_2\text{m nm}$ (no. 136), with a globally centrosymmetric crystal structure (Fig. 1a). The crystal structure is the same as that of IrO\textsubscript{2}, the SHE of which has been measured recently\textsuperscript{27}, although the two materials differ in that RuO\textsubscript{2} is an antiferromagnet while IrO\textsubscript{2} is non-magnetic. The band-structures of both materials contain Dirac nodal lines protected by non-symmorphic symmetries\textsuperscript{28–29}, which have the potential to generate strong SHEs. Recently, RuO\textsubscript{2} has also drawn considerable attention with the discovery of strain-stabilized superconductivity\textsuperscript{30–31}, anomalous antiferromagnetism\textsuperscript{32–33}, a crystal Hall effect\textsuperscript{14,35} and predictions of a magnetic SHE\textsuperscript{23} and giant tunnelling magnetoresistance\textsuperscript{16,37}.
Within the structure of RuO$_2$ (Fig. 1a), the Ru atoms at the centre and corners of the unit cell have opposite spins, forming a collinear antiferromagnetic (AF) ordering with the Néel vector $\vec{N}$ oriented along the [001] or [001] axis (with perhaps a small canting)$^{22,23}$. The centre and corner Ru atoms experience different oxygen environments, which leads to spin-split bands, as shown schematically in Fig. 1b$^{23}$. As a result of this spin-split band-structure, theory predicts that, when an electric field $E$ is applied, it can generate a spin current through an AF-SHE, even in the absence of any spin–orbit interaction (SOI). An example is shown in Fig. 1c, in which electric field $E$ applied along the $X$ axis ([010] direction) produces a spin current flowing along $Y$ ([100] direction) with spin polarization along $Z$ ([001] direction). This result is qualitatively similar to the conventional SHE in heavy metals, which is even under time reversal ($T$-even). However, the origin of the AF-SHE is fundamentally different because it does not require SOI and it is odd under time reversal ($T$-odd). If the crystal axes are rotated differently relative to the sample plane, the spin current can be calculated by an appropriate rotation of a spin Hall conductivity (SHC) tensor (Supplementary Section 4). In general, the flow of the spin current from this AF-SHE in RuO$_2$ will have a spin orientation $\hat{s}$ pointing approximately along $\vec{N}$, regardless of the electric field and spin-flow directions. RuO$_2$ possesses spin–orbit coupling, so it can also generate a $T$-even spin–orbit torque. Our density functional theory calculation results (shown in Fig. 1d) predict that, in a single-domain RuO$_2$ antiferromagnet, the $T$-odd SHC should be almost an order of magnitude larger than the $T$-even SHC, given the SOI of RuO$_2$, and the spin orientation produced by the $T$-even mechanism is not determined by $\vec{N}$ (Supplementary Section 4). These results are consistent with the prediction of ref. $^{23}$. A $T$-odd transverse spin current in magnetic systems is generally referred to as a magnetic SHE$^{13,18,38}$.

Based on the geometry of the $T$-odd AF-SHE predicted for RuO$_2$, we expect very different symmetries for the $E$-induced torques depending on whether the Néel vector is oriented out of plane or canted partially into the sample plane. For (001)-oriented RuO$_2$ films, $\vec{N}$ and hence the $E$-generated spin orientation $\hat{s}$ should point approximately perpendicular to the sample plane (Fig. 1e). Because the flow of spin current generated by the AF-SHE in RuO$_2$ must be perpendicular to the [001] direction, the $T$-odd AF-SHE mechanism should not generate any spin current flowing vertically toward the Py layer, and hence should not produce any spin-transfer torque related to the Néel vector in the (001)-oriented case. Therefore, for this geometry, the dominant $E$-induced torque should be the conventional torque generated by SOI, driven by a spin polarization oriented in-plane and perpendicular to $E$, that is, in the $Y$ direction, or [100] for Fig. 1e. This can lead to both an in-plane damping-like (DL) torque with the symmetry $\tau^D_{\text{DL}} = -\tau^D_{\text{DL},0}(\hat{m} \times \hat{Y} \times \hat{m})$ and/or an out-of-plane field-like (FL) torque $\tau^Y_{\text{FL}} = -\tau^Y_{\text{FL},0}(\hat{m} \times \hat{Y})$. We define signs as in ref. $^{39}$. With these choices of sign, a positive $\tau^D_{\text{DL},0}$ corresponds to the sign of the SHE for Pt, and $\tau^Y_{\text{FL},0}$ is positive for the Oersted field. All torques quoted are per unit magnetic moment with sign $\tau \propto \vec{d} \vec{n} / dt$.}

For a (101)-oriented RuO$_2$ film, on the other hand, the [001] axis is canted away from the out-of-plane direction with components along both the out-of-plane [101]$^*$ and in-plane [100] directions (Fig. 1f). The consequence of the AF-SHE spin-splitter mechanism in this case can be understood simply by visualizing the diagram in Fig. 1e rotated about the [010] axis. The flow of the spin current is still perpendicular to the [001] axis and the spin polarization $\hat{s}$ remains parallel to the [001] axis, but now, because of the canting
of the [001] axis, both the spin polarization and flow have components both perpendicular to the sample plane and in the sample plane. This geometry therefore allows the AF-SHE in RuO2 to be distinguished clearly from the conventional SHE in non-magnetic materials. If we define the X direction as parallel to the applied electric field \( E \) and the Z direction as out of plane, then, depending on the orientation of \( E \) relative to the crystal axes, the AF-SHE can produce SHC with non-zero components \( \sigma_{XZ}^Y \) (generating, for example, in-plane damping-like torque), \( \sigma_{XX}^Y \) (generating, for example, \( \tau_{DL}^Y = \sigma_{DL}^Y (\hat{n} \times \hat{X} \times \hat{m}) \)) and \( \sigma_{XX} \) (generating, for example, \( \tau_{DL}^X = \sigma_{DL}^X (m \times Z \times \hat{m}) \)). A symmetry analysis of the SHC tensor (Supplementary Section 4) predicts that the components of damping-like torque generated by the AF-SHE will follow a signature angular-dependence pattern. In a (101)-oriented RuO2 film, if the \( E \)-generated spin \( \hat{s} \) is oriented at an angle \( \theta \), tilted away from the out-of-plane (\( Z=[010]^* \)) axis towards the [100] direction and \( E \) is applied at an angle \( \psi \) with respect to the in-plane [010] axis, the components of damping-like torque efficiencies per unit electric field generated by the ASHE should follow

\[
\tau_{DL,E}^Y = \frac{2e}{\hbar} \mu_s M_{s,FM} \frac{\gamma}{E} C_1 \sin^2 \theta \cos^2 \psi + C_0,
\]

\[
\tau_{DL,E}^X = \frac{2e}{\hbar} \mu_s M_{s,FM} \frac{\gamma}{E} C_1 \cos \theta \sin \theta \cos \psi,
\]

\[
\tau_{DL,E}^X = \frac{2e}{\hbar} \mu_s M_{s,FM} \frac{\gamma}{E} C_1 \sin^2 \theta \cos \psi \sin \psi,
\]

where \( C_0 \) and \( C_1 \) are constants, \( M_s \) is the saturation magnetization, \( t_{FM} \) is the thickness of the ferromagnetic layer and \( \gamma \) is the gyromagnetic ratio. (The \( C_1 \) term can be generated by conventional SHE, independent of AF-SHE.)

In micrometre-scale devices of the sort we study, we expect to have many AF domains, with nearly equal numbers having \( \mathcal{N} \) pointing along [001] and [101]. If the fractions of the two domain variants are exactly equal, this should lead to zero \( \mathcal{T} \)-odd spin current. Nonetheless, in a multi-domain scenario, we can still obtain either a non-zero \( \mathcal{T} \)-odd SHC due to imperfect cancellation between domains or a non-zero \( \mathcal{T} \)-even SHC due to non-zero SOI. We will refer to a non-trivial spin Hall torque with a well-defined spin orientation \( \hat{s} \) (and therefore following the signature angular dependence in equations (1) to (3)) as an AF-SHE for either the \( \mathcal{T} \)-odd or \( \mathcal{T} \)-even mechanism.

**Techniques for extracting E-induced torque vectors**

To investigate the SHC of RuO2, we measure the \( E \)-induced torques acting on an in-plane-magnetized NiFe(001) (Py) layer (4 nm) deposited by sputtering on top of epitaxial RuO2 thin films (3–9 nm). We analyse films grown on both (001)- and (101)-oriented TiO2 substrates to study different orientations of the Néel vector relative to the sample plane. Details of sample preparation are provided in Methods and Supplementary Section 1.

We measure the \( E \)-generated torques in Py/RuO2 bilayers using angle-dependent spin-torque ferromagnetic resonance (ST-FMR)\(^{[11,44]}\), and we verify the results using the in-plane-anisotropy harmonic Hall (HH)\(^{[31]}\) technique. For ST-FMR measurements, the Py/RuO2 bilayer is patterned into a wire with microwave-compatible contacts, as shown in Fig. 1g. On each sample chip we make several devices oriented at different angles relative to the crystal axes to vary the angle \( \psi \) of \( E \) relative to the [010] direction. We apply a fixed-frequency microwave current and sweep an in-plane magnetic field at an angle \( \phi \) with respect to the current flow direction (Fig. 1g), repeating the measurement for each
sample for field angles from $\phi = -90^\circ$ to $270^\circ$ in steps of $15^\circ$. Torques acting on the magnet from the microwave current induce magnetic precession and corresponding resistance oscillations due to the bilayer's anisotropic magnetoresistance. Mixing between the resistance oscillations and the oscillating current results in d.c. voltage signals near resonance, the magnetic-field dependence of which can be fit to the sum of the symmetric and antisymmetric Lorentzian peak shapes
\[ V_S = S \left( \frac{\Delta^2}{(H-H_0)^2 + \Delta^2} \right) \] and \[ V_A = A \left( \frac{(H-H_0)\Delta}{(H-H_0)^2 + \Delta^2} \right) \]

(Fig. 2a). Amplitudes $S$ and $A$ are related to the in-plane and out-of-plane $E$-induced torques, $\Delta$ is the linewidth and $H_0$ is the resonant field. In the most general case when the spin polarization that generates the $E$-induced torque has components along all of the $X$, $Y$ and $Z$ axes, the allowed angular dependences for the coefficients $S$ and $A$ are
\[ S = S^X_{DL} \cos \phi \sin 2\phi + S^Y_{DL} \sin \phi \sin 2\phi + S^Z_{DL} \sin 2\phi, \]
\[ A = A^X_{FL} \cos \phi \sin 2\phi + A^Y_{FL} \sin \phi \sin 2\phi + A^Z_{FL} \sin 2\phi, \]

where $S^X_{DL}$, $S^Y_{DL}$ and $S^Z_{DL}$ are coefficients for the damping-like torque generated by the SHCs, $A^X_{FL}$, $A^Y_{FL}$ and $A^Z_{FL}$ are their field-like-torque counterparts (and $A^X_{FL}$ also contains the contribution from the Oersted torque). In our samples we can tell that the Oersted field is the dominant source for $A^X_{FL}$ because there is good agreement between the measured strength of the out-of-plane field-like torque and the estimated contribution from the Oersted field due to the current flow through the RuO$_2$ layer (Supplementary Sections 2 and 3). In this case, we can use the value of $A^Y_{FL}$ as a measure of the current density in the RuO$_2$, which allows us to quantify the amplitude of the damping-like torque efficiencies per unit current density in the RuO$_2$ ($j$) as
\[ \xi^X_{DL,j} = \frac{S^X_{DL}}{A^X_{FL}, \mu_0 M_{eff} \xi \mu \rho_{xx}}, \]
\[ \xi^Y_{DL,j} = \frac{S^Y_{DL}}{A^Y_{FL}, \mu_0 M_{eff} \xi \mu \rho_{xx}}, \]
\[ \xi^Z_{DL,j} = \frac{S^Z_{DL}}{A^Z_{FL}, \mu_0 M_{eff} \xi \mu \rho_{xx}}. \]

Here, $\mu_0 M_{eff}$ is the magnetic anisotropy (0.86 ± 0.03 T for the (101) devices and 0.68 ± 0.04 T for the (001) devices) measured by performing ST-FMR for a sequence of microwave frequencies and fitting the resonance fields to the Kittel equation. The saturation magnetization is $\mu_0 M_s = 0.87 ± 0.02$ T, as measured by vibrating sample magnetometry, and $\xi_{HM}$ and $\xi_{FL}$ are the thicknesses of the RuO$_2$ and Py, respectively. The damping-like torque efficiencies per unit applied electric field ($\xi^X_{DL,j}$) for each component of torque $k$ can be obtained by dividing the resistivity $\rho_{xx}$ of the RuO$_2$ film:
\[ \xi^X_{DL,j} = \frac{\xi^X_{DL}}{\mu_0 M_{eff} \xi \mu \rho_{xx}}. \]

For 6-nm-thick RuO$_2$, at room temperature, $\rho_{xx}$ is ~140 $\mu$Ω cm for (101)-oriented films and 275 $\mu$Ω cm for (001) films (compared to 70 $\mu$Ω cm for the 4-nm-thick Py). The components of the torque efficiencies per unit applied electric field $\xi^X_{DL,j}$ should be equal to the corresponding components of the SHC tensor $\sigma_{XX}$ times an interfacial spin transparency that is less than or equal to 1.

For the in-plane HH method, we apply a low-frequency alternating current (1.327 Hz) and measure both the first- and second-harmonic Hall voltages as a function of the angle of rotation $\phi$ of an in-plane magnetic field (Fig. 1g). The a.c. current generates alternating torques that result in oscillations in the Hall resistance due to the planar Hall effect and anomalous Hall effect. Mixing between the oscillating Hall resistance and the a.c. current results in a second-harmonic signal that can be expressed as
\[ V_{XY}^{2,1} = D^X_{DL} \cos \phi + D^Y_{DL} \sin \phi + D^Z_{DL} \cos 2\phi + F^X_{FL} \cos \phi \cos 2\phi + F^Y_{FL} \sin \phi \sin 2\phi + F^Z_{FL}. \]

Damping-like torques generated by the $X$, $Y$ and $Z$ components give rise to $D^X_{DL}$, $D^Y_{DL}$ and $D^Z_{DL}$ respectively, and the field-like torque counterparts give rise to $F^X_{FL}$, $F^Y_{FL}$ and $F^Z_{FL}$. The contributions from $E$-induced torques are distinguished from thermoelectric voltages based on their dependence on the magnetic-field magnitude. Supplementary Section 2 provides details of how the SHCs are calculated based on the HH measurements.

**E-induced torques for different crystal orientations of RuO$_2**

Figure 2b shows the $\phi$ dependence of the ST-FMR amplitudes $S$ (red squares) and $A$ (blue circles) for a (001)-oriented RuO$_2$ (6 nm)/Py(4 nm) sample where $E$ is applied along the [001] axis. This is the crystal orientation for which $N$ is oriented out of plane so that the AF-SHE should produce no unconventional $E$-induced torque on the Py layer either by the $T$-odd or $T$-even mechanism. We find that this is indeed the case. Both the symmetric component $S$ and the antisym-
metric component \( A \) can be fitted well simply using the conventional torque terms \( \propto \cos \phi \sin 2\phi \) that occur in ordinary heavy metals\(^{36}\). The strength of the symmetric term corresponds to a spin torque efficiency per unit electric field for a \((101)\text{RuO}_2(6\ \text{nm})/\text{Py}(4\ \text{nm})\) sample as a function of \( \psi \) (Fig. 2c), and the corresponding torque efficiency

\[
\zeta_{\text{DL}}(\theta) = \left| \frac{\Delta A(\psi)}{\Delta F(\psi)} \right|
\]

as determined from equation (7).

The ST-FMR results for a \((101)\)-oriented \(\text{RuO}_2(6\ \text{nm})/\text{Py}(4\ \text{nm})\) sample, the geometry for which \( N' \) is tilted away from the out-of-plane direction, are shown in Fig. 2c–h. The data for \( E \) in the [010] direction (\( \psi = 0^\circ \) within alignment accuracy) are presented in Fig. 2c,d. The symmetric component of the ST-FMR signal has an angular dependence similar to the (001) sample; only the conventional damping-like SHE term \( \zeta_{\text{DL}} = \propto \sin 2\phi \) is required to fit the results (Fig. 2c), and the corresponding torque efficiency is \( \zeta_{\text{DL}}(\phi) = (3.6 \pm 0.6) \times 10^3 (\Omega \text{m})^{-1} \) (or \( \zeta_{\text{DL}}(\phi) = 0.049 \pm 0.008 \)).

Note, however, that the antisymmetric component is very different than for the (001)-oriented film. For the \((101)\)-oriented case, \( A \) cannot be fit only by the \( A_{\text{DL}} \) \( \cos \phi \sin 2\phi \) term; there is also a significant \( A_{\text{DL}} \sin 2\phi \) contribution corresponding to an out-of-plane damping-like torque (with \( \zeta_{\text{DL}}(\phi) = (7 \pm 1) \times 10^3 (\Omega \text{m})^{-1} \)). This additional term is also consistent with our HH measurements (Fig. 2g) as \( V_{\text{AX}} \) requires the term \( D_{\text{EL}} \) \( \cos 2\phi \) for the fitting in addition to the conventional fitting function\(^2 \). \( D_{\text{DL}} \) \( \cos \phi \phi + F_{\text{FL}} \cos \phi \phi \cos 2\phi \) (Supplementary Section 2). In contrast, when \( E \) is applied along the [101] axis (\( \psi = 90^\circ \)) for the \((101)\)-oriented case, we observe only conventional spin torques, that is, \( \zeta_{\text{DL},E} \neq 0 \), \( \zeta_{\text{DL},E} \approx 0 \), \( \zeta_{\text{DL},E} \approx 0 \), and \( \zeta_{\text{DL},E} \approx 0 \), as both the \( S \) and \( A \) amplitudes in ST-FMR can be fit by \( \cos \phi \sin 2\phi \) (Fig. 2c,f), and \( Y_{\text{AX}} \) in the HH measurement can be fit by \( D_{\text{EL}} \) \( \cos \phi + F_{\text{FL}} \cos \phi \phi \cos 2\phi \) (Fig. 2b).

For the intermediate values of \( \psi \) we find from ST-FMR measurements that the spin-torque efficiencies have the angular dependence shown in Fig. 3a–c. The behaviours of all three components are in excellent agreement with equations (1)–(3) for fitting parameters \( C_0 = (26 \pm 4) \times 10^3 (\Omega \text{m})^{-1} \), \( C_1 = (14 \pm 2) \times 10^3 (\Omega \text{m})^{-1} \) and \( \theta = 44 \pm 5^\circ \). This complete signature angular dependence, which corresponds to an \( E \)-induced spin current with tilted spin, has thus been verified experimentally in \( \text{RuO}_2 \). This is the most important result of this Article. It is a signature that the torques are indeed due to a spin current with a tilted spin orientation. Furthermore, the orientation of \( z \) is close to the optimum angle for maximizing the out-of-plane damping-like torque, \( 45^\circ \) according to equation (3).

We can identify the \( \psi \)-dependent torques as being generated by the AF order in \( \text{RuO}_2 \), by comparing to measurements on (101)-oriented \( \text{IrO}_2 \) films, which are isostuctural with \( \text{RuO}_2 \), but non-magnetic. The (101)-oriented \( \text{IrO}_2 \) films generate only conventional spin–orbit torques, with a non-zero value of \( \zeta_{\text{DL},E} \) but with \( \zeta_{\text{DL},E} \neq 0 \) and \( \zeta_{\text{DL},E} = 0 \) (Fig. 4a). The lowered symmetry provided by the canted Néel vector of \( \text{RuO}_2 \) is therefore essential for the existence of the unconventional torque terms.

We mentioned above that the \( E \)-induced spin \( z \) is expected to be only approximately parallel to the Néel vector \( N' \), as shown in
Fig. 1. This is not expected to be exact, because deviation from the Néel vector orientation can be generated by SOI. Assuming that \( \mathcal{N} \) is oriented along the [001] direction of the RuO\(_2\) crystal, and given the lattice constants of bulk RuO\(_2\) (0.311 nm in the [001] direction and 0.449 nm in the [100] and [010] perpendicular directions), in a (101)-oriented film, the tilt angle of \( \mathcal{N} \) relative to the out-of-plane direction should be \( \sim 35^\circ \), a smaller tilt angle than for the spin orientation \( \tilde{z} \) indicated by the angular dependence in Fig. 3. This difference is qualitatively consistent with our density functional theory calculations, suggesting that for the AF-SHE, \( \tilde{z} \) is tilted from \( \mathcal{N} \) for a (101)-oriented film by about \( 5^\circ \) within the (010) plane due to SOI, which generates additional spin current components non-collinear to the Néel vector (Supplementary Section 4). Other possible contributions that might alter \( \theta \), slightly are that \( \mathcal{N} \) might not be oriented strictly along the [001] direction as reported in ref. 22, epitaxial strain can modify the lattice parameters slightly, and the interface spin transmission factor could depend on the orientation of the spin, so that spin absorbed by the ferromagnetic layer to generate the E-induced torque might not be exactly aligned with the spin orientation of the spin current within the RuO\(_2\) layer. Related measurements of E-induced torque in (100)- and (110)-oriented RuO\(_2\)/ferromagnet bilayers, which are also consistent with a spin polarization approximately parallel to \( \mathcal{N} \), have also recently been reported 22.

We measured the damping-like E-induced torques for different thicknesses of the (101)-oriented RuO\(_2\) films (3–9 nm) as shown in Fig. 4b for measurements with \( \psi=0^\circ \) (filled squares) and \( \psi=90^\circ \) (open circles). Both the conventional (\( \varphi \)-independent) and unconventional (\( \varphi \)-dependent) torque efficiencies increase with increasing RuO\(_2\) thickness, suggesting that the E-induced spin current originates in the bulk of the RuO\(_2\) film and not at the RuO\(_2\)/Py interface. The approach to saturation at larger thicknesses suggests a spin diffusion length \( \xi \) of 2.6±0.3 nm in the RuO\(_2\). Additional evidence for a bulk generation mechanism comes from samples in which we inserted a thin Ir spacer between the RuO\(_2\) and the Py (the full structure was RuO\(_2\)(9 nm)/Ir(1 nm)/Py(4 nm)/Ir(1 nm)). In this case we still observe non-zero values of both \( \xi_{\text{E}}^\text{DL} = 3.5\pm0.7 \times 10^4 (\Omega \text{ m}^{-1}) \) and \( \xi_{\text{DL}}^\varphi = 3.3\pm0.6 \times 10^4 (\Omega \text{ m}^{-1}) \) for \( \varphi=0^\circ \) (Fig. 4c). Based on the evidence presented so far, we have not determined whether the unconventional E-induced torques generated by RuO\(_2\) correspond to a \( T \)-odd or a \( T \)-even spin current. Because the AF order in RuO\(_2\) allows both effects, and they could both generate spin currents with a well-defined orientation \( \varphi \), giving a qualitatively similar dependence on the angle \( \varphi \) (although, for the \( T \)-even effect, \( \varphi \) is not expected to be correlated to the Néel vector; Supplementary Section 4). Our measured SHCs are approximately a factor of 50 smaller than the prediction for the \( T \)-odd spin current from a uniform single-domain RuO\(_2\) sample (Fig. 1d and ref. 23), but this could be due to nearly complete cancellation between domains with \( \mathcal{N} \) in the [001] and [010] directions, structural disorder or a reduction in the electron relaxation time below the value assumed in the calculation. For the \( T \)-odd mechanism to apply, as we noted above there must in fact be a small but consistent imbalance in the distribution of [001] and [010] domains, similar to the lack of complete cancellation between domains in other recent studies of spin torques from different antiferromagnets 22,24. We also cannot rule out a contribution from the \( T \)-even spin current based just on the amplitude of the torques, even though the predicted value is much smaller than the \( T \)-odd spin current, because the predicted value of the \( T \)-even torque is similar to the order of magnitude that we report here.

To help distinguish the \( T \)-odd and \( T \)-even mechanisms, we measured the out-of-plane damping-like SHC as a function of temperature (Fig. 4d). We observe a strong enhancement as a function of decreasing temperature. This is suggestive that the \( T \)-odd spin current is dominant, as this should be enhanced as the electron lifetime increases at low temperature (Supplementary Section 4). Conventional \( T \)-even SHCs arising from intrinsic SHEs generally have negligible temperature dependence for moderately low-resistivity materials like (101) RuO\(_2\) (ref. 22). We observe a non-zero out-of-plane damping-like torque up to at least 400 K (Fig. 4d), confirming that AF ordering in RuO\(_2\) persists up to this temperature 22,23.

Even with the likelihood that the strength of the out-of-plane damping-like torque is reduced by cancellations between domain variants or other disorder, the strength of the effect is still among the largest of all materials that have been measured. For 6-nm-thick (101)-oriented RuO\(_2\), from Fig. 3b we measure a maximum room-temperature value for the out-of-plane damping-like spin-torque efficiency per unit electric field of \( \xi_{\text{E}}^\text{DL} = (7\pm1) \times 10^4 (\Omega \text{ m}^{-1}) \) (compared to, for example, \( (3.6\pm0.8) \times 10^4 (\Omega \text{ m}^{-1}) \) for WTe\(_2\) (ref. 24) and \( (1.02\pm0.03) \times 10^4 (\Omega \text{ m}^{-1}) \) for MoTe\(_2\) (ref. 25)). The only materials for which we are aware of a slightly larger out-of-plane damping-like spin-torque efficiency are the non-collinear antiferromagnet Mn\(_3\)GaN (ref. 26) with \( \xi_{\text{E}}^\text{DL} \approx 8.6 \times 10^4 (\Omega \text{ m}^{-1}) \) and (114)-textured MnPd\(_2\) (ref. 27) with \( \xi_{\text{E}}^\text{DL} \approx 1.4 \times 10^4 (\Omega \text{ m}^{-1}) \).

Our results are indeed due to a \( T \)-odd spin current, the strength of the out-of-plane damping-like torque in RuO\(_2\) might be increased substantially by controlling the AF domains to more strongly favour one of the domain variants (\( \mathcal{N} \) parallel to [001] or [010]) over the other.

Conclusions

We have shown that (101)-oriented films of the collinear antiferromagnet RuO\(_2\) can produce a substantial electric-field-generated out-of-plane damping-like torque on an adjacent permalloy film. The spin torques acting on the permalloy film were measured using ST-FMR and HH measurements. By analysing the dependence of the torques on the angles of both the electric field and the magnetic field relative to the crystal axes, we have shown that the torque is associated with a spin polarization approximately parallel to the Néel vector of the RuO\(_2\). This angular dependence is the signature of an AF-SHE predicted for RuO\(_2\) (ref. 25).

Methods

Sample preparation. The RuO\(_2\) thin films were prepared by reactive-oxide molecular beam epitaxy in a background pressure of 3×10\(^{-6}\) torr of distilled oxygen (~80% O\(_3\), ~20% O\(_2\)) at a substrate temperature of 300°C. The films were then transported in air to a sputtering system with a base vacuum better than 2×10\(^{-10}\) torr, and 4 nm of Py was deposited at 30 mW power and 2 mtorr Ar pressure. To protect the Py layer from oxidation, we capped the Py with a 1.2 nm layer of Ta, which naturally oxidizes to TaO\(_3\). Devices were then patterned by optical lithography and argon-ion milling such that electric current could be applied at different angles \( \varphi \) with respect to the crystal axes. Electrical contacts for Ti(5 nm)/Pt(75 nm) were made by optical lithography, sputtering and liftoff. For the ST-FMR studies, the electrical contacts were in the form of a microwave-compatible ground–source–ground geometry (Fig. 1g), and the dimensions of the ST-FMR device under test were 30 \( \mu\text{m} \times 20 \mu\text{m} \times 25 \mu\text{m} \) (length × width). The HH measurements on the Hall bars were 20 \( \mu\text{m} \) and 6 \( \mu\text{m} \). Further details of sample preparation and characterization are provided in Supplementary Section 1.

HH measurements. For second-harmonic Hall measurements on (101)-oriented RuO\(_2\)/Py samples, the current axis of the Hall bar for different devices was aligned at various angles relative to the [001] crystal axis on the same sample chip (\( \varphi = 0^\circ \), 30°, 45°, 60°, 90°, 120°, 135° and 150°). We applied a low-frequency alternating current \( I = f \Delta I \cos(2\pi ft) \) (with \( f = 1.327 \text{ Hz} \)) and an in-plane magnetic field \( H_\text{in} \) at various angles \( \varphi \) relative to the current flow direction, and measured the first- and second-harmonic voltages using a lock-in amplifier. We investigated fixed values of \( \mu_0 H_\text{in} \) ranging from 50 to 300 mT, applied by a GMW projected-field magnet on a Newport motion-controlled stage. Further details of the measurements and analysis are provided in Supplementary Section 2.

ST-FMR measurements. For the ST-FMR measurements, we also patterned different devices on the same sample chip so that the applied microwave current had different angles, \( \varphi \), relative to the crystallographic axes, as shown in Supplementary Fig. 1a. For each device, an in-plane magnetic field was swept from...
Calculation of spin Hall conductivities. We calculate the atomic and electronic structures of RuO$_2$, using the projector augmented-wave (PAW) method$^{46}$ implemented in the VASP code$^{46}$. A plane-wave cutoff energy of 500 eV and a 1×16×16 k-point mesh in the irreducible Brillouin zone were used in the calculations. The exchange and correlation effects were treated within the generalized gradient approximation (GGA) developed by Perdew–Burke–Ernzerhof (PBE)$^{47}$. The GGA+U functional$^{19}$ with $U_{\text{Ru}}=2\, \text{eV}$ on Ru 4d orbitals and $U_{\text{O}}=5\, \text{eV}$ on Ti 3d orbitals was included in all the calculations. The SOI was included in all the calculations. We used the tight-binding Hamiltonians obtained from the maximally localized Wannier functions$^{27}$ within the Wannier90 code$^{28}$. The time-reversal odd and even parts of SHC are given by$^{29,30}$

\[
\sigma^{0\delta}_{ij} = -\frac{2}{\hbar} \int \frac{d\mathbf{k}}{8\pi} \sum_{\alpha,\alpha'} \frac{\Gamma_{\delta\delta}(\mathbf{k})}{\Gamma_{\delta\delta}(\mathbf{k})} \oint \frac{d\mathbf{l}}{4\pi} \left( \mathbf{v}_{\alpha}(\mathbf{k}) \times \mathbf{v}_{\alpha'}(\mathbf{k}) \right) \cdot \mathbf{l},
\]

and

\[
\sigma^{1\delta}_{ij} = -\frac{2}{\hbar} \int \frac{d\mathbf{k}}{8\pi} \sum_{\alpha,\alpha'} \frac{\Gamma_{\delta\delta}(\mathbf{k})}{\Gamma_{\delta\delta}(\mathbf{k})} \oint \frac{d\mathbf{l}}{4\pi} \left( \mathbf{v}_{\alpha}(\mathbf{k}) \times \mathbf{v}_{\alpha'}(\mathbf{k}) \right) \cdot \mathbf{l},
\]

where $\frac{\hbar}{2}(v, \mathbf{k})$ is the spin-current operator, $\mathbf{f}_{\delta\delta}$ is the Fermi-Dirac distribution function for band $\delta$ and wavevector $\mathbf{k}$, and $v_{\alpha}$ and $v_{\alpha'}$ are velocity and spin operators, respectively, and $\alpha, \alpha' = x, y, z$. A 500×500×500 k-point mesh was used for the integral of equations (11) and (12). When calculating the $T$-odd SHC in equation (11), a constant $\Gamma$ that determines the broadening magnitude was used, which can be estimated by comparing the calculated conductivity with the experimental conductivity. For RuO$_2$, the room-temperature conductivities are 3.600 $\Omega^{-1}\text{cm}^{-1}$ for the (001) film and 6.900 $\Omega^{-1}\text{cm}^{-1}$ for the (101) film, corresponding to $\Gamma \approx 50\, \text{meV}$ and $\Gamma \approx 25\, \text{meV}$, respectively. When calculating the $T$-even SHC in equation (12), the adaptive smearing method$^{31}$ was used. Results of the calculations are presented in Supplementary Section 4.
