1. Introduction

Because they have anisotropic interactions and electronic properties, low-dimensional systems often show intriguing physical behaviours. Despite a low critical temperature ($T_c$) of 4.6 K [1], the newly discovered quasi-one-dimensional (quasi-1D) superconductor Ta$_4$Pd$_3$Te$_{16}$ has been labelled as an unconventional superconductor from scanning tunnelling microscopy (STM) [2] and thermal conductivity [3] experiments, from which an anisotropic gap structure with possible nodes has been proposed. This result is quite intriguing since the electronic states of typical unconventional superconductors at the Fermi level are derived from $d$ or $f$ bands while a recent density functional theory (DFT) study on Ta$_4$Pd$_3$Te$_{16}$ indicates that they mainly originate from Te $p$ states in this material with only little contribution from $d$ electrons from transition metal elements [4]. In addition, quasi-1D systems are particularly prone to the formation of a static charge-density-wave (CDW) or a static spin-density-wave (SDW), often regarded as states in competition with superconductivity. Not only does the electronic structure contain nested Te $p$ bands, which would be favourable to a CDW rather than a SDW [4], a CDW-like gap feature has also been reported from low-temperature STM measurements on stripes of Te atoms [5]. CDW fluctuations are thus a potential candidate for the pairing glue in Ta$_4$Pd$_3$Te$_{16}$ that would in principle favour a singlet state [4] and strong electron–phonon interactions.

In order to investigate the strength of the electron–phonon coupling and the possible existence of a CDW instability, here we present a Raman scattering study of Ta$_4$Pd$_3$Te$_{16}$ supported by first-principles calculations of the vibration modes. We observed 28 out of 33 Raman active modes, with frequencies in good accordance with first-principles calculations. Although most of the phonons observed vary only slightly with temperature and do not exhibit any asymmetric profile that would suggest strong electron–phonon coupling, the linewidth of the $A_g$ phonon mode at 89.9 cm$^{-1}$ shows an unconventional increase with temperature decreasing, which is possibly due to a charge-density-wave transition or the emergence of charge-density-wave fluctuations below a temperature estimated to fall in the 140–200 K range.

with temperature, except for one $A_g$ phonon at 89.9 cm$^{-1}$. We show that this particular mode, associated to vibrations of Te located along the stripes where a CDW-like gap was observed from STM [5], splits in the 140–200 K temperature range and below, which is possibly related to a CDW transition or CDW fluctuations.

2. Experiment

The Ta$_4$Pd$_3$Te$_{16}$ single crystals used in our Raman scattering measurements were prepared by a self-flux method [1]. The shiny, soft, layered samples have a typical dimension of $2.5 \times 0.1 \times 0.05$ mm$^3$, as shown in figure 1(a). Raman scattering measurements were performed using 488.0 nm, 514.5 nm, 530.9 nm, 568.2 nm and 676.5 nm laser excitations in a back-scattering micro-Raman configuration with a triple-grating spectrometer (Horiba Jobin Yvon T64000) equipped with a nitrogen-cooled CCD camera. At room temperature a 100× objective was used to both focus the laser beam and collect the scattered light whereas a long-focus distance 50× objective was used for measurements in the low-temperature cryostat. The crystals were cleaved by tape to obtain clean and flat surfaces, and then transferred into a low-temperature ST500 (Janis) cryostat for the Raman measurements between 5 and 350 K with a working vacuum better than $2 \times 10^{-6}$ mbar. In this paper we use the primitive cell represented by the black line in figure 1(b), which differs from the unit cell used in previous reports [6, 7] on this material (grey line). We define $Y$ and $Z$ as the directions along the $b$ and $c$ axes, respectively. The $Y$ direction corresponds to the PdTe$_2$ chains direction. The natural cleaved surface of this crystal is the Ta–Pd–Te layer, i.e. the $bc$ plane, as evidenced by STM measurements [2].

**Figure 1.** (a) Photo of a Ta$_4$Pd$_3$Te$_{16}$ single crystal. The inset shows the crystal structure viewed perpendicularly to the sample surface. (b) Crystal structure of Ta$_4$Pd$_3$Te$_{16}$ viewed perpendicularly to the $b$-axis. The black parallelogram represents the primitive cell used in our Raman measurements, while the grey one refers to another unit cell commonly used. All the atoms in the primitive cell are identified by numbers. The incident light is perpendicular to the $bc$ plane.

functions. Using the generalized gradiant approximation estimates on the mode frequencies of Ta₄Pd₃Te₁₆, we employed the first-principles pseudopotential plane wave method package Quantum Espresso [9]. We set a phonon frequencies and vibration modes of the I point. The calculated phonon modes, their symmetries and the main atomic displacements involved, are given in table 1.

In figures 2(a) and (b), we show the Raman spectra of Ta₄Pd₃Te₁₆ recorded at room temperature under 488.0 nm, 514.5 nm, 530.9 nm, 568.2 nm and 676.5 nm laser excitations. In total, we observe no less than 28 of the 33 Raman active modes predicted. The scattered intensities of the five absent modes are too weak to be detected. As indicated in table 1, the

Note: The energies are given in cm⁻¹. The atoms are identified in figures 1(b).
For perfectly aligned crystals, pure $A_g$ symmetry is obtained in the (YY) configuration. In this channel, we detect 19 peaks at 26.4 cm$^{-1}$, 41.4 cm$^{-1}$, 46.8 cm$^{-1}$, 58.3 cm$^{-1}$, 65.7 cm$^{-1}$, 74.5 cm$^{-1}$, 81.9 cm$^{-1}$, 89.9 cm$^{-1}$, 99.4 cm$^{-1}$, 109.6 cm$^{-1}$, 120.8 cm$^{-1}$, 128.8 cm$^{-1}$, 139.5 cm$^{-1}$, 150.2 cm$^{-1}$, 154.2 cm$^{-1}$, 168.1 cm$^{-1}$, 185.3 cm$^{-1}$, 192 cm$^{-1}$ and 206.5 cm$^{-1}$. They correspond to vibrations of atoms in the $bc$ plane. Pure $B_g$ symmetry is obtained in the (YZ) configuration. In this channel, we detect 9 peaks at 28.4 cm$^{-1}$, 52.7 cm$^{-1}$, 61.6 cm$^{-1}$, 89.1 cm$^{-1}$, 97.3 cm$^{-1}$, 103.3 cm$^{-1}$, 105.2 cm$^{-1}$, 127.9 cm$^{-1}$, and 161.2 cm$^{-1}$. They correspond to vibrations of atoms along the $b$-axis. The symmetric peak profiles that we observe suggest that the electron–phonon coupling is not particularly strong in this system.

We also checked how the peak intensities vary away from perfect orientation. Assuming, in a first approximation, that the matrix elements of the Raman tensors are real numbers, the intensity of the $A_g$ modes should vary with the angle $\theta$ between the $b$ axis and the incident polarization vector $\mathbf{e}_i$ as $|b \cos^2 \theta + c \sin^2 \theta|^2$ and $|b - c \sin 2\theta|^2$ for parallel and cross polarization configurations, respectively. For the cross polarization configuration, this implies a four-fold symmetry with maxima at 45 degrees and each successive 90 degrees, which is exactly what we observe for the $A_g$ peak at 41.4 cm$^{-1}$, as shown in the inset of figure 2(a). For the parallel configuration, the expected angular dependence of the $A_g$ peaks depends on the relative sign and intensity of the $b$ and $c$ elements in the Raman tensor. For the peak at 41.4 cm$^{-1}$, we observe small maxima at $\theta = 0$ and $\theta = 180$ degrees, a larger maximum at $\theta = 90$ degrees and four-fold minima starting at $\theta = 45$ degrees. This situation is possible if $b$ and $c$ have a different sign and $|c/b| > 1$. Indeed, we found $c/b = -1.5$ from the fitting of the experimental data. The intensity of the $B_g$ mode peaks should be proportional to $|f \sin 2\theta|^2$ and $|f \cos 2\theta|^2$ for parallel and cross polarization configurations, respectively. This coincides in both cases with four-fold oscillations, with the first maximum at $\theta = 45$ degrees and $\theta = 0$ degrees, respectively, in agreement with the results illustrated in the inset of figure 2(b) for the $B_g$ peak at 61.6 cm$^{-1}$.

To investigate the possible role of the electron–phonon coupling and the possible existence of a CDW order, we cooled the samples down to 5 K. In figures 3(a) and 4(a), we display the temperature dependence of the $A_g$ peaks and $B_g$ peaks, respectively. As expected, most peaks are slightly blue shifted and become a little sharper with temperature decreasing, except for the $A_g$ peak at 89.9 cm$^{-1}$ that we discuss below. We show in figure 3(b), a quantitative analysis of the peak position and the linewidth of the $A_g$ Raman peak at 128.8 cm$^{-1}$, which has been fitted with a Lorentzian function. The results of similar analysis are also shown in figures 4(b) and (c) for the $B_g$ mode at 61.6 cm$^{-1}$. The peak position $\omega_{ph}(T)$ and the linewidth $\Gamma_{ph}(T)$ are consistent with simple expressions corresponding to the anharmonic phonon decay into acoustic phonons with the same frequencies and opposite momenta [14, 15]:

\[
A_g = \begin{pmatrix} a & 0 & d \\ b & 0 & 0 \\ d & c & 0 \end{pmatrix}, \quad B_g = \begin{pmatrix} 0 & e & 0 \\ e & 0 & f \\ 0 & f & 0 \end{pmatrix},
\]
We observe 28 out of 33 Raman frequency, and of the $B_g$ mode at 61.6 cm$^{-1}$ in figure 3(a), the linewidth of the $A_g$ peak at 128.8 cm$^{-1}$ is well fitted with the formulae

$$\omega_{\text{ph}}(T) = \omega_0 - C \left( 1 + \frac{2}{\hbar \omega_0} \frac{e^{\frac{h \omega_0}{k T}} - 1}{e^{\frac{h \omega_0}{k T}} - 1} \right)$$

$$\Gamma_{\text{ph}}(T) = \Gamma_0 + \Gamma \left( 1 + \frac{2}{\hbar \omega_0} \frac{e^{\frac{h \omega_0}{k T}} - 1}{e^{\frac{h \omega_0}{k T}} - 1} \right),$$

where $C$ and $\Gamma$ are positive constants, $\omega_0$ is the bare phonon frequency, and $\Gamma_0$ is a residual, temperature-independent linewidth. From the fits, we extract $\omega_0 = 137.1$ cm$^{-1}$,

$C = 0.1755$ cm$^{-1}$, $\Gamma_0 = 3.496$ cm$^{-1}$ and $\Gamma = 0.05918$ cm$^{-1}$ for the $A_g$ peak at 128.8 cm$^{-1}$. Similarly, the position and linewidth of the $B_g$ peak at 61.6 cm$^{-1}$ is well fitted with the formulae

with $\omega_0 = 64.96$ cm$^{-1}$, $C = 0.153$ cm$^{-1}$, $\Gamma_0 = 1.614$ cm$^{-1}$ and $\Gamma = 0.02442$ cm$^{-1}$.

Ignoring the $A_g$ peak at 89.9 cm$^{-1}$, we could conclude the absence of CDW in this system. However, as shown in figure 3(a), the linewidth of the $A_g$ peak at 89.9 cm$^{-1}$ fitted with a single Lorentzian function exhibits an unusual increase, almost exponential, upon cooling. To emphasize this point, we show in the inset of figure 3(c) the spectra of this peak at 5 K obtained from two different samples and two different laser excitations. Interestingly, the peak splits into two peaks at low temperature, which can explain the unusual increase of the linewidth observed upon cooling. It is important to notice that the peak at 89.9 cm$^{-1}$ has the $A_g$ symmetry and is by definition non-degenerate. In addition, no other peak that we did not observe is expected around that energy. The observation of a new peak is thus most likely caused by a lowering of the symmetry of the system. In that sense, the new peak emerging at low temperature may be related to the CDW-like gap feature observed at 4 K by STM [5]. Indeed, the $A_g$ phonon at 89.9 cm$^{-1}$ represents the vibration of Te$^4$, Te$^5$, Te$^6$, Te$^7$ and Te$^8$, among which are atoms located at the bright and dark stripes observed by Du et al in STM measurements [2], where the CDW-like gap feature is detected. If this is really the origin of the peak splitting, we estimate that the CDW transition temperature or the temperature at which CDW fluctuations emerge is somewhere between 140 K and 200 K, the temperature range where the linewidth of the 89.9 cm$^{-1}$ starts to increase. Unfortunately, the proximity of the two-peak components prevents us from performing a reliable fit of the 89.9 cm$^{-1}$ feature using two Lorentzian functions at such high temperature. Further experiments such as electron diffraction experiments should be done in the future to confirm the existence of the CDW and test its relationship to superconductivity.

4. Summary

In summary, we have performed polarized Raman scattering measurements on the newly discovered superconductor TaPd$_3$Te$_6$ ($T_c = 4.6$ K). We observe 28 out of 33 Raman active modes, with frequencies in good accordance with our first-principles calculations. Most of the phonons that we observe vary only slightly with temperature except for one $A_g$ phonon at 89.9 cm$^{-1}$. The linewidth of the $A_g$ phonon mode at 89.9 cm$^{-1}$ shows an unconventional increase with temperature decreasing, which is possibly due to a CDW transition or to CDW fluctuations.
