Caspase-11 Activation in Response to Bacterial Secretion Systems That Access the Host Cytosol

Abstract
Inflammasome activation is important for antimicrobial defense because it induces cell death and regulates the secretion of IL-1 family cytokines, which play a critical role in inflammatory responses. The inflammasome activates caspase-1 to process and secrete IL-1β. However, the mechanisms governing IL-1α release are less clear. Recently, a non-canonical inflammasome was described that activates caspase-11 and mediates pyroptosis and release of IL-1α and IL-1β. Caspase-11 activation in response to Gram-negative bacteria requires Toll-like receptor 4 (TLR4) and TIR-domain-containing adaptor-inducing interferon-β (TRIF)-dependent interferon production. Whether additional bacterial signals trigger caspase-11 activation is unknown. Many bacterial pathogens use specialized secretion systems to translocate effector proteins into the cytosol of host cells. These secretion systems can also deliver flagellin into the cytosol, which triggers caspase-1 activation and pyroptosis. However, even in the absence of flagellin, these secretion systems induce inflammasome activation and the release of IL-1α and IL-1β, but the inflammasome pathways that mediate this response are unclear. We observe rapid IL-1α and IL-1β release and cell death in response to the type IV or type III secretion systems of Legionella pneumophila and Yersinia pseudotuberculosis. Unlike IL-1β, IL-1α secretion does not require caspase-1. Instead, caspase-11 activation is required for both IL-1α secretion and cell death in response to the activity of these secretion systems. Interestingly, whereas caspase-11 promotes IL-1β release in response to the type IV secretion system through the NLRP3/ASC inflammasome, caspase-11-dependent release of IL-1α is independent of both the NAIP5/NLRC4 and NLRP3/ASC inflammasomes as well as TRIF and type I interferon signaling. Furthermore, we find both overlapping and non-redundant roles for IL-1α and IL-1β in mediating neutrophil recruitment and bacterial clearance in response to pulmonary infection by L. pneumophila. Our findings demonstrate that virulent, but not avirulent, bacteria trigger a rapid caspase-11-dependent innate immune response important for host defense.

Abstract

Inflammasome activation is important for antimicrobial defense because it induces cell death and regulates the secretion of IL-1 family cytokines, which play a critical role in inflammatory responses. The inflammasome activates caspase-1 to process and secrete IL-1β. However, the mechanisms governing IL-1β release are less clear. Recently, a non-canonical inflammasome was described that activates caspase-11 and mediates pyroptosis and release of IL-1α and IL-1β. Caspase-11 activation in response to Gram-negative bacteria requires Toll-like receptor 4 (TLR4) and TIR-domain-containing adaptor-inducing interferon-β (TRIF)-dependent interferon production. Whether additional bacterial signals trigger caspase-11 activation is unknown. Many bacterial pathogens use specialized secretion systems to translocate effector proteins into the cytosol of host cells. These secretion systems can also deliver flagellin into the cytosol, which triggers caspase-1 activation and pyroptosis. However, even in the absence of flagellin, these secretion systems induce inflammasome activation and the release of IL-1α and IL-1β, but the inflammasome pathways that mediate this response are unclear. We observe rapid IL-1α and IL-1β release and cell death in response to the type IV or type III secretion systems of Legionella pneumophila and Yersinia pseudotuberculosis. Unlike IL-1β, IL-1α secretion does not require caspase-1. Instead, caspase-11 activation is required for both IL-1α secretion and cell death in response to the activity of these secretion systems. Interestingly, whereas caspase-11 promotes IL-1β release in response to the type IV secretion system through the NLRP3/ASC inflammasome, caspase-11-dependent release of IL-1α is independent of both the NAIP5/NLRC4 and NLRP3/ASC inflammasomes as well as TRIF and type I interferon signaling. Furthermore, we find both overlapping and non-redundant roles for IL-1α and IL-1β in mediating neutrophil recruitment and bacterial clearance in response to pulmonary infection by L. pneumophila. Our findings demonstrate that virulent, but not avirulent, bacteria trigger a rapid caspase-11-dependent innate immune response important for host defense.

Introduction

Antibacterial defense is initiated by germline-encoded pattern recognition receptors (PRRs), which detect conserved pathogen-associated molecular patterns (PAMPs) [1–3]. Plasma membrane-bound PRRs, such as the Toll-like receptors (TLRs), detect PAMPs present in the extracellular space and endosomal compartments, whereas cytosolic PRRs, such as the NOD-like receptors (NLRs), survey the host cytosol for the presence of invasive pathogens [3–7]. Invasive microorganisms or other cellular stresses induce assembly of cytosolic protein complexes known as inflammasomes, which play a critical role in host defense [8–11]. Inflammasomes respond to a wide variety of activators, including bacterial pore-forming toxins and bacterial PAMPs, such as flagellin or RNA [12–18]. Particular NLRs respond to their cognate stimuli and recruit the adapter protein ASC and pro-caspase-1 through homotypic protein-protein interactions between pyrin domains and caspase recruitment domains (CARD), leading to autoprocessing and activation of caspase-1 [19–23]. Caspase-1 is responsible for processing and secreting IL-1 family cytokines and mediates a proinflammatory cell death termed pyroptosis [9,11,24,25].

Caspase-11 participates in the activation of a non-canonical inflammasome that induces cell death and the secretion of IL-1α and IL-1β in response to Gram-negative pathogens, such as Escherichia coli and Vibrio cholerae, and to particular toxins, such as the cholera toxin B subunit [26–29]. This non-canonical, caspase-11-dependent response to Gram-negative bacteria is independent of virulence-associated secretion systems that deliver bacterial molecules into the host cytosol and requires LPS-induced TLR4 signaling through the adaptor TRIF-domain-containing adaptor-inducing interferon-β (TRIF) and TRIF-dependent type I interferon (IFN) production. Type I IFN signaling through the type I IFN receptor (IFNAR) is required for caspase-11...
Author Summary

The inflammasome, a multiprotein complex, is critical for host defense against bacterial infection. The inflammasome activates the host protease caspase-1 to process and secrete IL-1β. Another caspase, caspase-11, can cause cell death and IL-1α release. The bacterial signals that trigger caspase-11 activation are poorly understood. A common feature of many bacterial pathogens is the ability to inject virulence factors and other bacterial molecules into the host cell cytosol by means of a variety of virulence-associated secretion systems. These secretion systems can introduce bacterial flagellin into the host cytosol, which leads to caspase-1 activation and cell death. However, many bacteria lack or down-regulate flagellin yet still activate the inflammasome. Here, we show that the type IV secretion system of Legionella pneumophila and the type III secretion system of Yersinia pseudotuberculosis rapidly trigger caspase-11 activation in a flagellin-independent manner. Caspase-11 activation mediates two separate inflammasome pathways: one leading to IL-1β processing and secretion, and one leading to cell death and IL-1α release. Furthermore, we find these caspase-11-regulated cytokines are critical for neutrophil recruitment to the site of infection and clearance of non-flagellated Legionella in vivo. Overall, our findings show that virulent bacteria activate a rapid caspase-11-dependent immune response that plays a critical role in host defense.

upregulation and activation, but how type I IFN mediates activation of caspase-11 is not well-defined [27–29]. Caspase-11 contributes to NLRP3-dependent activation of caspase-1 and subsequent caspase-1-dependent IL-1β secretion and cell death. Caspase-11 also facilitates an NLRP3- and caspase-1-independent pathway that results in cell death and release of IL-1α [26–29]. This caspase-11-dependent, caspase-1-independent pathway is responsible for LPS-induced septic shock in vivo [26,30]. Although caspase-11 is activated in response to signals from Gram-negative pathogens and certain pore-forming toxins, whether caspase-11 contributes to inflammasome activation in response to virulence-associated secretion systems that deliver bacterial ligands into host cytosol is unknown.

Bacterial pathogens use evolutionarily conserved secretion systems, such as type III or type IV secretion systems (T3SS or T4SS), to translocate effector proteins into the cytosol of host cells [31,32]. In addition to bona fide virulence factors, these secretion systems also translocate bacterial molecules such as flagellin or structural components of the secretion machinery itself, which results in inflammasome activation [14,16,33–36]. Legionella pneumophila, an opportunistic pathogen that causes a severe pneumonia known as Legionnaires’ disease [37,38], utilizes its dot/icm-encoded T4SS as a virulence factor to translocate bacterial effector proteins into the host cell cytosol and establish a replicative vacuole [39–46]. L. pneumophila induces T4SS-dependent inflammasome activation through two genetically distinct pathways [47]. T4SS-mediated translocation of flagellin into the cytosol triggers caspase-1 activation and pyroptosis through the NLR NAIP5 in conjunction with another NLR, NLRC4 [16,36,47–50]. Caspase-1 activation is also triggered independently of the NLRC4/flagellin pathway through the adaptor protein ASC, but the bacterial factor that is recognized and the upstream proteins that regulate this pathway remain unknown [47,51]. However, although ASC is necessary for robust secretion of IL-1β in response to L. pneumophila as well as a number of pathogens, such as Salmonella or Yersinia species which employ T3SSs, ASC is dispensable for induction of pyroptosis that is rapidly triggered in response to these infections. We therefore considered the possibility that in addition to its role in delayed inflammasome activation in response to Gram-negative bacteria, caspase-11 might participate in rapid cell death and release of IL-1α in response to the presence of bacterial pathogens that access the host cell cytosol by means of type IV and type III secretion systems.

Here, we demonstrate that IL-1α and IL-1β are rapidly released in response to bacterial T4SS activity independently of bacterial flagellin. In this system, we find IL-1β secretion requires caspase-1, but caspase-1 is dispensable for cell death and IL-1α release in response to a functional L. pneumophila T4SS. Instead, caspase-11 is required for both IL-1α release and cell death in response to L. pneumophila T4SS activity. Consistent with recent findings, caspase-11 contributes to optimal NLRP3-mediated caspase-1 activation and IL-1β secretion in response to L. pneumophila. However, caspase-11-dependent IL-1α release and cell death in L. pneumophila-infected cells are independent of the NAIP5/NLRC4 and NLRP3/ASC inflammasomes. In contrast to the role of TRIF and IFNAR in the response against Gram-negative bacteria, caspase-11 activation and cytokine release in response to the T4SS of L. pneumophila are independent of both TRIF and IFNAR signaling. We further demonstrate that T3SS activity of the unrelated pathogen Yersinia pseudotuberculosis induces a similarly rapid caspase-11-dependent response that also leads to cell death and release of IL-1α and IL-1β. Finally, we find that both IL-1α and IL-1β are critical in vivo for neutrophil recruitment and bacterial clearance. Overall, our data show that caspase-11 is poised to respond robustly to a conserved feature of pathogenic bacteria, bacterial access to the host cytosol through specialized secretion systems. This establishes caspase-11 as a critical regulator of immune system-mediated discrimination of pathogenic and nonpathogenic bacteria.

Results

LPS priming induces rapid IL-1α and IL-1β secretion in response to L. pneumophila T4SS activity

L. pneumophila infection induces IL-1α and IL-1β secretion that requires T4SS activity [47,52]. IL-1β secretion is regulated by a flagellin-dependent NAIP5/NLRC4 inflammasome and a poorly defined ASC inflammasome that both activate caspase-1 [47,51]. The mechanisms underlying IL-1α secretion are less clear, but IL-1α secretion is still robustly induced by flagellin-deficient L. pneumophila, which do not activate the NAIP5/NLRC4 inflammasome [52]. Recent studies have described a non-canonical inflammasome triggered in response to Gram-negative bacteria. This non-canonical inflammasome requires lipopolysaccharide (LPS) for the upregulation and activation of caspase-11 and subsequent IL-1α and IL-1β release [26–29]. Whether caspase-11 is also activated in response to bacteria that use specialized secretion systems to translocate bacterial molecules into the host cytosol is unknown. We thus hypothesized that LPS priming would upregulate caspase-11, pro-IL-1α, and pro-IL-1β and allow for more robust and rapid IL-1α and IL-1β secretion in response to T4SS activity. To test this, we first compared IL-1α and IL-1β release in unprimed and LPS-primed bone marrow-derived macrophages (BMDMs). As shown previously [48,52], unprimed BMDMs secrete robust levels of IL-1α and IL-1β by 20 hours post-infection with wild-type L. pneumophila (WT Lp) (Figure 1A). Slightly attenuated levels of secreted IL-1α and IL-1β are observed with flagellin-deficient L. pneumophila (Af41 Lp), which do not activate the NAIP5/NLRC4 inflammasome [17,18]. Secretion of both
cytokines is significantly diminished during infection with \( L. \) pneu
mophila lacking DotA, an essential component of the T4SS (ΔdotA Lp), and is significantly diminished in caspase-1/caspase-11-deficient \((\text{Casp}^1\text{-}\text{Casp}11^-)\) macrophages as well (Figure 1A). The diminished IL-1 secretion induced by ΔdotA Lp is not due to a lack of pro-IL-1 production, as ΔdotA Lp and WT Lp induce robust levels of pro-IL-1β (Figure S1A). At 4 hours post-infection, unprimed macrophages do not secrete IL-1 (Figure 1B). However, LPS-primed cells rapidly secrete IL-1α and IL-1β, and this secretion is abrogated in \( \text{Casp}^1\text{-}\text{Casp}11^- \).
macrophages (Figure 1B). Secretion of IL-18, another IL-1 family cytokine, also requires T4SS activity and is eliminated in Casp1/-/-/Casp11/-/- cells (Figure S1B). Comparable levels of the caspase-1/caspase-11-independent cytokines IL-12 and TNF-α are secreted in the absence and presence of LPS priming (Figure S1C–D). These data suggest that LPS priming upregulates a factor required for rapid IL-1α and IL-1β release in response to L. pneumophila T4SS activity.

Caspase-1 catalytic activity is required for IL-1β but not IL-1α secretion

Secretion of IL-1β in response to both canonical and non-canonical inflammasome activation requires caspase-1 [26,53,54]. In contrast, IL-1α release downstream of the non-canonical inflammasome depends on caspase-11, and does not require caspase-1 [26]. To test if the catalytic activity of caspase-1 is required for IL-1α secretion in response to L. pneumophila, we inhibited caspase-1 catalytic activity with the pharmacological inhibitor YVAD-cmk (YVAD). Consistent with previous studies [53], IL-1β secretion in response to L. pneumophila is substantially inhibited by YVAD. However, YVAD has no effect on IL-1α secretion, indicating that IL-1α release in response to L. pneumophila does not require caspase-1 catalytic activity (Figure 1C), as has been shown for other inflammasome activators [55]. Given that IL-1α secretion occurs more rapidly upon LPS priming, is abrogated in Casp1/-/-/Casp11/-/- macrophages, and does not require caspase-1 catalytic activity, we considered the possibility that caspase-11 might participate in inflammasome activation during L. pneumophila infection.

Caspase-11 contributes to inflammasome activation in response to flagellin-deficient L. pneumophila

To test the genetic requirement for caspase-11 in the inflammasome response to L. pneumophila, we infected BMDMs from either caspase-1-deficient (Casp1-/-) or caspase-11-deficient (Casp11-/-) mice. In the absence of flagellin, caspase-11 is required for IL-1α secretion, whereas it is not essential for IL-1β secretion but contributes to maximal secretion (Figure 2A). These data suggest that caspase-11 is activated in response to L. pneumophila infection independently of flagellin. Indeed, there is robust processing and secretion of caspase-11 in response to WT

Figure 2. Caspase-11 controls the release of IL-1α and IL-1β and pyroptosis in response to flagellin-deficient L. pneumophila. B6, Casp1-/-, Casp11-/-, or Casp11-/- BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT L. pneumophila (WT Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) or treated with 2.5 mm ATP for 1(C) or 4(A,B) hours. (A) Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. (B) Cell death (% cytotoxicity) was measured by LDH release into the supernatants relative to Triton X-100-lysed cells. Graphs show the mean ± SEM of triplicate wells. (C) Levels of processed caspase-1 (casp-1 p10) in the supernatants and full-length caspase-1 (pro-casp-1) and β-actin in the cell lysates were determined by immunoblot analysis. Data are representative of three independent experiments. *** is p<0.001 by two-way ANOVA with Bonferroni post-test, ** is p<0.01 by two-way ANOVA with Bonferroni post-test, and * is p<0.05 by unpaired t-test. NS is not significant.

doi:10.1371/journal.ppat.1003400.g002
and ΔflaA Lp (Figure S2). In accordance with previous findings [26,33], caspase-1 is absolutely required for IL-1β secretion. In contrast, we observe robust IL-1α release even in the absence of caspase-1. Both IL-1α and IL-1β release in response to ΔflaA Lp are caspase-11-dependent in both primed and unprimed macrophages (Figures 2, S3A–B), making L. pneumophila distinct from other Gram-negative bacteria that require priming to induce robust caspase-11 upregulation and activation [27]. Thus, while caspase-11 contributes to maximal caspase-1-dependent IL-1β secretion, it is both necessary and sufficient for IL-1α release in response to flagellin-deficient L. pneumophila.

Cell death in B6 BMDMs is partially flagellin-dependent, but is flagellin-independent in Gasp1−/− BMDMs (Figure 2B). Importantly, cell death in response to flagellin-deficient L. pneumophila requires caspase-11, thus correlating caspase-11-dependent cell death with IL-1α release from host cells. In contrast, and consistent with previous findings [26], LPS+ATP induces canonical caspase-1-dependent pyroptosis and secretion of IL-1α and IL-1β that is independent of caspase-11. Because caspase-1 must be processed to mediate IL-1β secretion [53], we examined whether caspase-1 processing is decreased in the absence of caspase-11, which could account for the decreased IL-1β secretion in response to ΔflaA Lp. Caspase-1 processing is slightly attenuated but not abrogated in response to ΔflaA Lp in Gasp1−/− macrophages, consistent with the slight decrease in IL-1β secretion (Figures 2C, S3C). Thus, flagellin-deficient L. pneumophila triggers a canonical caspase-1-dependent inflammasome as well as a non-canonical caspase-11-dependent inflammasome.

**Caspase-11 activation is independent of ASC and NLRC4**

The ASC and NAIP5/NLRC4 inflammasomes are required for caspase-1 activation and IL-1β secretion in response to L. pneumophila [47]. To determine if these inflammasomes are also required for caspase-11 activation and IL-1α release, we infected ASC/NLRC4-deficient (Asc−/−,Nlrc4−/−) BMDMs with L. pneumophila. Asc−/−,Nlrc4−/− BMDMs do not secrete IL-1β in response to either WT Lp, ΔflaA Lp, or LPS+ATP. However, Asc−/−,Nlrc4−/− BMDMs still release IL-1α in response to ΔflaA Lp in primed and unprimed macrophages (Figures 3A, S4). Thus, unlike IL-1β, IL-1α is released independently of flagellin, ASC, and NLRC4. Accordingly, despite an absence of processed caspase-1 p10, robust levels of processed caspase-11 p26 are detected in the supernatants of Asc−/−,Nlrc4−/− cells infected with either WT or ΔflaA Lp but not in response to LPS+ATP (Figure 3B).

We next sought to determine whether IL-1α is also released independently of ASC and NLRC4 during in vivo infection. Because flagellin-deficient L. pneumophila do not activate the NLRC4 inflammasome [16,17,47], infecting Asc−/− mice with ΔflaA Lp eliminates both the ASC and NLRC4 inflammasome pathways. Importantly, the level of IL-1β in the bronchoalveolar lavage fluid (BALF) 24 hours post-infection is significantly attenuated in Asc−/− mice infected with ΔflaA Lp (Figure 3C). In contrast, the level of IL-1α in the BALF is unaffected even in the absence of both the ASC and NLRC4 inflammasomes. Both IL-1α and IL-1β release are significantly diminished in caspase-1/caspase-11-deficient mice (Figure S5). Collectively, our data indicate that L. pneumophila triggers caspase-11 activation and IL-1α release independently of the ASC and NLRC4 inflammasomes during both in vitro and in vivo infection.

**Caspase-11 mediates both NLRP3-dependent and NLRP3-independent inflammasome responses**

L. pneumophila induces caspase-1 activation and IL-1β and IL-18 secretion through two genetically distinct pathways, one involving ASC and one involving NLRC4 (Figures 4A, S6A–B) [47]. The upstream host and bacterial components of the ASC-dependent response to L. pneumophila are still unknown, but are independent of the flagellin/NAIP5/NLRC4 pathway (Figures 4A, S6B) [47]. Because caspase-11 contributes to maximal IL-1β secretion in response to ΔflaA Lp, we further investigated the ASC-dependent mechanism of inflammasome activation. NLRP3, an NLR involved in inflammasome-dependent responses to a wide variety of pathogens, requires ASC to mediate caspase-1 processing during both canonical and non-canonical inflammasome activation [9,12,18,26,56]. We therefore investigated the role of NLRP3 in the response to ΔflaA Lp. Notably, IL-1β and IL-18 secretion are abrogated during infection of NLRP3-deficient (Nlrp3−/−) BMDMs with ΔflaA Lp in both primed and unprimed macrophages (Figures 4B, S7A–C). Consistently, we do not detect processed caspase-1 p10 in the supernatants of Nlrp3−/− macrophages infected with ΔflaA Lp (Figure 4C). Thus, NLRP3 functions together with ASC, caspase-1, and caspase-11 to control IL-1β secretion in response to flagellin-deficient L. pneumophila. However, IL-1α release and cell death following infection with flagellin-deficient L. pneumophila are independent of NLRP3 (Figures 4B, S7A), indicating that caspase-11 also mediates an NLRP3-independent response towards flagellin-deficient L. pneumophila. Accordingly, NLRP3-dependent IL-1β secretion in response to flagellin-deficient L. pneumophila was inhibited by extracellular potassium, whereas NLRP3-independent caspase-11-dependent IL-1α secretion and cell death were not affected (Figure S7D–E).

**Non-canonical inflammasome responses to L. pneumophila occur independently of TRIF and IFNAR**

Recent data demonstrate that caspase-11 activation in response to a wide variety of Gram-negative bacteria requires TLR4 signaling through its adaptor TRIF and subsequent type I IFN production [27–29]. To determine if L. pneumophila engages a similar TRIF and type I IFN receptor (IFNAR)-dependent pathway for caspase-11 activation, we infected TRIF-deficient (Trif−/−) and IFNAR-deficient (Ifnar−/−) BMDMs. Unlike the response to E. coli, L. pneumophila infection of unprimed macrophages triggered robust cell death and secretion of IL-1α and IL-1β that was independent of IFNAR and TRIF (Figure 5A–B). Consistently, priming with the TLR1/2 agonist Pam3CSK4, which results in TRIF- and IFNAR-dependent cytokine secretion and cell death in response to E. coli [27], still induced cell death and cytokine secretion in TRIF- and IFNAR-deficient cells in response to L. pneumophila (Figure S8A–B). These data suggest that during L. pneumophila infection, caspase-11 is upregulated and activated independently of TRIF and IFNAR signaling. Indeed, caspase-11 is still robustly processed and secreted independently of IFNAR and TRIF (Figures 5C, S9). Notably, substantially upregulated levels of pro-caspase-11 are not observed in the lysates of cells infected with WT or ΔflaA Lp because both the pro and cleaved forms of caspase-11 are rapidly secreted into the cell supernatant upon infection (Figures 5C, S9). Accordingly, lysates from IFNAR- and TRIF-deficient macrophages infected with L. pneumophila express comparable levels of pro-caspase-11 to wild-type macrophages, whereas TRIF and IFNAR do contribute to upregulation of pro-caspase-11 in response to E. coli (Figure S10A–C). When the macrophages are primed with LPS prior to infection, there is a moderate contribution of TRIF and IFNAR signaling to inflammasome activation, consistent with the observation that LPS stimulates the TLR4-TRIF-IFNAR axis involved in caspase-11 upregulation (Figure S8C–D). Because the caspase-11-dependent response to L.
pneumophila is TRIF-independent, we investigated whether the TLR signaling adaptor MyD88 contributes to caspase-11 upregulation. When immortalized macrophages deficient for both MyD88 and Trif (Myd88<sup>−/−</sup> Trif<sup>−/−</sup>) were infected, caspase-11 upregulation was abrogated in response to both WT and ΔflaA Lp (Figure S11A–B), and we were unable to detect caspase-11 activation (data not shown). Thus, although TRIF is not required for caspase-11 activation, a TLR-dependent signal is likely required as the loss of both MyD88 and TRIF eliminates caspase-11 upregulation and activation.

**Figure 3. Caspase-11 activation is independent of ASC and NLRC4.** (A) Unprimed B6, Casp1<sup>−/−</sup> Casp11<sup>−/−</sup>, or Asc<sup>−/−</sup> Nlrc4<sup>−/−</sup> BMDMs were infected with WT L. pneumophila (WT Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 20 hours, and levels of IL-1α and IL-1β in the supernatants were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. (B) Unprimed B6, Casp1<sup>−/−</sup> Casp11<sup>−/−</sup>, or Asc<sup>−/−</sup> Nlrc4<sup>−/−</sup> BMDMs were infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 20 hours or treated with LPS+ATP for 1 hour. Levels of processed caspase-1 (casp-1 p10) and caspase-11 (casp-11 p26) in the supernatants, and pro-caspase-1, pro-caspase-11, and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. (C) 8–12 week old B6 and Asc<sup>−/−</sup> mice were infected intranasally with either 1×10<sup>6</sup> ΔflaA Lp or PBS. Bronchoalveolar lavage fluid (BALF) was collected 24 hours post-infection, and levels of IL-1α and IL-1β were measured by ELISA. Graphs show the mean ± SEM of 9 mice per group. Dashed line represents the limit of detection. Data are representative of three independent experiments (A,B) or are displayed as the pooled results of two independent experiments (C). *** is p<0.001 by two-way ANOVA with Bonferroni post-test. ** is p<0.01 by unpaired t-test. Caspase-11 mediates inflammasome activation in response to *Yersinia pseudotuberculosis* type III secretion system activity

Because caspase-11 activation in response to *L. pneumophila* expressing a functional T4SS is so rapid and robust, we sought to test whether this robust caspase-11-dependent inflammasome activation might be a general response to the activity of specialized secretion systems that allow for bacterial access to the host cytosol. The *Yersinia pseudotuberculosis* type III secretion system (T3SS) induces inflammasome activation independently of bacterial flagellin and the known secreted effector proteins, and this inflammasome activation is important for bacterial clearance [57]. Since wild-type *Yersinia* induces cell death that is independent of both caspase-1 and -11 and requires the secreted effector YopJ [57,58], we instead infected Casp1<sup>-/-</sup>Casp11<sup>-/-</sup>, Asc<sup>-/-</sup>, or Asc<sup>-/-</sup>Nlrc4<sup>-/-</sup> BMDMs with a strain of *Y. pseudotuberculosis* that expresses a T3SS but lacks the six known secreted effectors (Δ6 Yp). Similarly to *L. pneumophila* infection, both IL-1α and IL-1β release in response to Δ6 Yp are caspase-11-dependent (Figure 6A). Again, caspase-1 is absolutely required for IL-1β secretion, whereas IL-1α is released independently of caspase-1. Secretion of IL-12, an inflammasome-independent cytokine, is unaffected (Figure S12). Cell death in response to Δ6 Yp is both caspase-1 and caspase-11-dependent, with a more dramatic reduction in death in Casp11<sup>-/-</sup> BMDMs (Figure 6B). Furthermore, *Y. pseudotuberculosis*-induced release of both IL-1α and IL-1β requires the presence of a functional T3SS, as *Y. pseudotuberculosis* unable to form a functional T3SS pore in the host cell plasma membrane (ΔyopB Yp) do not induce secretion of either cytokine. These data indicate a general role for caspase-11 in the induction of rapid cell death and robust release of IL-1α and IL-1β in response to bacterial secretion systems that are capable of accessing the host cell cytosol, but may be independent of the activities of specific virulence factors per se.

**IL-1α and IL-1β control bacterial burden and neutrophil recruitment in vivo**

As caspase-11 contributes to flagellin-independent IL-1α and IL-1β release from infected macrophages *in vitro* and IL-1α and IL-1β...
secretion is flagellin-independent in vivo, we wanted to determine the contribution of IL-1α and IL-1β to host defense against L. pneumophila in vivo. IL-1α and IL-1β both bind the IL-1 receptor (IL-1R), which signals through the MyD88 adaptor protein [59–61]. As MyD88 is critical for control of L. pneumophila replication during in vivo infection but deletion of an individual MyD88-dependent TLR or a combination of TLRs does not recapitulate MyD88 deficiency, it is likely that other MyD88-dependent receptors, including the IL-1R, may play a role [62–66]. IL-1R signaling contributes to chemokine production by non-hematopoietic cells during infection with wild-type, flagellin-expressing L. pneumophila [67]. However, the role of IL-1R

Figure 5. Non-canonical inflammasome responses to L. pneumophila occur independently of TRIF and IFNAR. (A) Unprimed B6, Ifnar−/−, or Trif−/− BMDMs were infected with WT L. pneumophila (WT Lp), ΔdotA Lp, Δ flaA Lp, E. coli, or PBS (mock infection) for 16 hours. Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. (B) Unprimed B6, Ifnar−/−, or Trif−/− BMDMs were infected with WT Lp, ΔdotA Lp, Δ flaA Lp, or PBS (mock infection) for 16 hours. Cell death (% cytotoxicity) was measured by LDH release into the supernatants relative to Triton X-100-lysed cells. Graphs show the mean ± SEM of triplicate wells. (C) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.4 μg/mL Pam3CSK4 for 4 hours and infected with WT Lp, ΔdotA Lp, Δ flaA Lp, or PBS for 16 hours. Levels of full-length caspase-11 (pro-casp-11) and processed caspase-11 (casp11 p26) in the supernatants and pro-casp-11 and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. Data are representative of two independent experiments. doi:10.1371/journal.ppat.1003400.g005

Figure 6. Caspase-11 mediates inflammasome activation in response to a functional Yersinia type III secretion system. BMDMs from B6, Casp1−/−, Casp11−/−, or Casp1−/− mice were primed with 0.05 μg/mL LPS for 4 hours and infected with type III secretion system-deficient Y. pseudotuberculosis (ΔyopB Yp), effecterless Y. pseudotuberculosis AHOJMEK (Δ6 Yp), or PBS (mock infection) or treated with 2.5 mm ATP for 4 hours. (A) Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. (B) Cell death (% cytotoxicity) was measured by lactate dehydrogenase (LDH) release relative to Triton X-100-lysed cells. Graphs show the mean ± SEM of triplicate wells. Data are representative of two independent experiments. *** is p<0.001 and ** is p<0.01 by two-way ANOVA with Bonferroni post-test. NS is not significant. doi:10.1371/journal.ppat.1003400.g006
signaling during infection with flagellin-deficient \textit{L. pneumophila}, which do not activate the NAIP5/NLRC4 inflammasome, has not been investigated. We therefore infected B6 and IL-1R-deficient (Il1r1\textsuperscript{-/-}) mice intranasally with \textit{DflaA} \textit{Lp} and measured bacterial burden in the lung over the course of seven days. Though both B6 and Il1r1\textsuperscript{-/-} mice received similar initial bacterial burdens, Il1r1\textsuperscript{-/-} mice show a defect in bacterial clearance as early as 24 hours post-infection (Figure 7A). Bacterial burden remains elevated in the absence of IL-1R signaling, with the Il1r1\textsuperscript{-/-} mice still exhibiting a log-increase in bacterial load at 120 hours post-infection. Since IL-1R signaling is important for neutrophil recruitment [68], we examined whether Il1r1\textsuperscript{-/-} mice have a defect in neutrophil recruitment to the pulmonary airspace during \textit{L. pneumophila} infection. Indeed, Il1r1\textsuperscript{-/-} mice exhibit a significant decrease in neutrophil recruitment to the airspace 24 hours post-infection, possibly contributing to their inability to efficiently clear the pathogen (Figure 7B–C).

The IL-1R signals in response to both IL-1\alpha and IL-1\beta; however, these cytokines can play non-redundant roles in antibacterial defense [69]. To determine the relative contributions of

**Figure 7. IL-1\alpha and IL-1\beta control bacterial burden and neutrophil recruitment in vivo.** (A) 8–12 week old B6 or Il1r1\textsuperscript{-/-} mice were infected with \textasciitilde{}10\textasciitilde{}^6 \textit{DflaA} \textit{L. pneumophila} intranasally (IN). Lungs were plated to quantify CFU per gram. Graph shows the mean \pm SEM of three or four infected mice per group. Dashed line represents the limit of detection. (B and C) B6 or Il1r1\textsuperscript{-/-} mice were infected with \textasciitilde{}10\textasciitilde{}^6 \textit{DflaA} \textit{Lp} IN. 24 hours post-infection, bronchoalveolar lavage fluid (BALF) was collected and the percentage of neutrophils in the BALF was quantified by flow cytometry. Percentages are reported as the frequency of live cells in the BALF. (B) Representative flow cytometry plots showing the percentage of Gr-1\textsuperscript{+}Ly6G\textsuperscript{+} neutrophils. (C) Graph showing the percentage of neutrophils. Each point represents an individual mouse and lines indicate the mean of 4 mice per group. (D, E, and F) B6 mice were injected intraperitoneally (IP) with either PBS, 100 \textmu g isotype control antibody (iso), 100 \textmu g anti-IL-1\alpha antibody, 100 \textmu g anti-IL-1\beta antibody, or 100 \textmu g each of anti-IL-1\alpha and anti-IL-1\beta (anti-IL-1\alpha/\beta) 16 hours before infection. The mice were then intranasally infected with either 1\times{}10\textasciitilde{}^6 \textit{DflaA} \textit{Lp} or mock infected with PBS. (D and E) 24 hours post-infection, BALF was collected and flow cytometry was performed to quantify the percentage of neutrophils. Each point represents an individual mouse and lines indicate the mean of 4 mice per group. (D) Representative flow cytometry plots showing the percentage of Gr-1\textsuperscript{+}Ly6G\textsuperscript{+} neutrophils. (E) Graph showing the percentage of neutrophils. Each point represents an individual mouse, lines indicate the mean of 8 mice per group, and error bars represent SEM. Shown are the pooled results of two independent experiments. (F) 72 hours post-infection, the lungs were plated to quantify CFU per gram. Each point represents an individual mouse. Line indicates the mean of 4 infected mice per group with error bars representing SEM. *** is p<0.001 by one-way ANOVA with Tukey post-test or unpaired t-test (C). ** is p<0.01 and * is p<0.05 by unpaired t-test. NS is not significant. doi:10.1371/journal.ppat.1003400.g007
IL-1α and IL-1β to neutrophil recruitment and bacterial clearance during *L. pneumophila* infection, we utilized neutralizing antibodies to selectively block either IL-1α or IL-1β prior to infection. Specific cytokine neutralization in the BALF could be observed 24 hours post-infection (Figure S13). Critically, IL-1α neutralization alone significantly diminishes the percentage of neutrophils recruited to the BALF at 24 hours post-infection and results in a half-log increase in bacterial CFUs, in marked contrast to isotype control antibody or neutralization of IL-1β, which on its own did not have a significant effect (Figure 7D–F). However, neutralization of both IL-1α and IL-1β fully recapitulates the magnitude of neutrophil reduction and defect in bacterial clearance observed in the *Il1r1<sup>−/−</sup>* mice. Collectively, these data indicate that although there are some overlapping roles for these cytokines during *L. pneumophila* infection, IL-1α plays a distinct role from IL-1β in driving neutrophil recruitment to the airway and mediating bacterial clearance.

**Discussion**

Inflammasomes respond robustly to conserved features of pathogenic microbes, such as pore-forming toxins or specialized secretion systems that access the host cytosol. Inflammasomes therefore play a central role in enabling the immune system to discriminate between virulent and avirulent bacteria [70]. Recent reports show a role for caspase-11 in regulating the activation of a non-canonical inflammasome that promotes cell death as well as IL-1α and IL-1β secretion. This non-canonical inflammasome

![Figure 8. Caspase-11 controls multiple pathways of inflammasome activation in response to bacterial secretion systems that access the host cytosol.](image-url)
responds to both pathogenic and non-pathogenic Gram-negative bacteria independently of specialized secretion systems that translocate bacterial molecules into the host cytosol [26–29]. This pathway involves the TRIF- and IFNAR-dependent upregulation and activation of caspase-11 and occurs with relatively delayed kinetics in comparison to the response to pathogenic bacteria. Intriguingly, we find that the activity of the L. pneumophila Dot/Icm T4SS leads to rapid and robust caspase-11 activation independently of the TRIF-IFNAR axis, and this activation triggers rapid cell death and release of both IL-1α and IL-1β (Figure 8). We extend these results to show that the evolutionarily distinct T3SS of another pathogen, Y. pseudotuberculosis, also rapidly triggers caspase-11-dependent responses. Collectively, our findings demonstrate that caspase-11 is critical for inflammasome activation in response to the secretion systems of virulent bacteria that enable bacterial molecules to access the host cell cytosol and demonstrate that IL-1α and IL-1β together play a crucial protective role during acute infection in vivo.

We demonstrate that in response to the activity of bacterial secretion systems that enable cytosolic access, caspase-11 contributes to NLRP3-mediated inflammasome activation and caspase-11-dependent IL-1β secretion and to a second ASC and NLRC4-independent pathway that does not require caspase-11 and leads to cell death as well as robust IL-1α release. These L. pneumophila-induced pathways are similar to recent findings with a number of Gram-negative bacterial pathogens, including C. rodentium, E. coli, and S. typhimurium [26–29]. However, we observe rapid and robust T4SS-dependent activation of these two caspase-11-mediated pathways by L. pneumophila, whereas the response to Gram-negative bacteria lacking specialized secretion systems occurs less robustly and with much slower kinetics. Intriguingly, we observe a similarly rapid caspase-11-dependent induction of cell death and IL-1 release in response to the structurally and evolutionarily unrelated T3SS of Y. pseudotuberculosis. Importantly, this pathway is independent of host sensing of flagellin, as it is triggered by flagellin-deficient L. pneumophila, and Y. pseudotuberculosis downregulates flagellin expression when the T3SS is expressed [71]. Thus, our data suggest that the caspase-11 inflammasome is poised to respond robustly and rapidly to the activity of bacterial secretion systems that are capable of delivering microbial products to the host cell cytosol and may enable the host to respond to pathogens that evade flagellin-dependent responses. This could have significance for understanding the role of caspase-11 activation at mucosal sites colonized by large numbers of commensal bacteria. At mucosal barriers, it would be expected that the non-canonical inflammasome pathway would not be robustly activated by commensal bacteria but could respond rapidly to the presence of bacterial secretion systems that enable pathogen access to the host cytosol.

Our findings are consistent with recent observations that the L. pneumophila Dot/Icm T4SS triggers the caspase-11-dependent non-canonical inflammasome [72], as well as the finding that bacteria that enter the cytosol either due to failure to maintain integrity of their replicative vacuoles or natural entry into the cytoplasm also trigger rapid caspase-11 activation [73]. Thus the pathway that leads to caspase-11 activation appears to be particularly sensitive to pathogens that ‘violate the sanctity of the cytosol’ [74], either through the activity of specialized secretion systems that translocate bacterial molecules into the cytosol or through their direct entry into the host cell cytosol. Whether other pathogens that replicate within the cytosol, such as Listeria or Shigella, or cytosolic viruses possess mechanisms to evade this pathway remains to be determined.

L. pneumophila T4SS-mediated activation of caspase-11 differs from the other pathways of non-canonical inflammasome activation in several ways. First, L. pneumophila-mediated activation of caspase-11 does not require TRIF or IFNAR signaling. We observe a moderate dependence on TRIF and IFNAR signaling when macrophages are primed with LPS prior to infection, consistent with LPS-dependent upregulation of caspase-11 expression through the TLR4-TRIF-IFNAR axis [27–29]. However, in the absence of LPS priming, TRIF and IFNAR signaling are dispensable for L. pneumophila-dependent caspase-11 activation. In this context, it is likely that MyD88 compensates for the absence of TRIF, as cells deficient for both MyD88 and TRIF failed to activate caspase-11 in response to L. pneumophila. Thus, although the TLR4-TRIF-IFNAR axis is required for caspase-11 activation in response to Gram-negative bacteria, a MyD88-dependent signal is sufficient for caspase-11 activation in response to pathogens that utilize virulence-associated secretion systems to translocate bacterial molecules into the host cytosol. It is possible that different signals are capable of activating caspase-11 through distinct pathways, but these pathways occur with distinct kinetics because they may indicate distinct levels of pathogenicity. Thus, while caspase-11 is robustly upregulated by LPS priming, this upregulation alone is insufficient for rapid activation in response to bacteria that lack specialized secretion systems, as Shigella or Y. pestis bacteria do not induce rapid cell death even in primed cells. Collectively, these data indicate a two-signal model for rapid caspase-11 activation during infection with virulent bacteria, where bacterial PAMPs induce caspase-11 upregulation, but rapid caspase-11 activation requires a second, secretion system-dependent signal (Figure 8).

The specific secretion system-dependent signals responsible for caspase-11 activation are currently unknown. While rapid activation of caspase-11 requires the presence of a functional type III or type IV secretion system or cytosolic access of the bacteria, whether the signal is an as-yet-undefined translocated bacterial molecule or a cellular response to the pore forming activity of these systems remains to be determined. The delayed NLRP3- and caspase-11-dependent response to Gram-negative bacteria suggests that in addition to LPS-induced upregulation of inflammasome components, bacterial mRNA provides an additional signal for activating the NLRP3 inflammasome [18,75], although the role of caspase-11 in this response has not been formally demonstrated. Activity of the type III or IV secretion systems may bypass the need for bacterial mRNA. Alternatively, these secretion systems may translocate bacterial RNA [70,76,77], and the rapid caspase-11-dependent response they induce could be due to more rapid delivery of bacterial mRNA into the host cell cytosol.

Furthermore, the host factors required for activation of the NLRP3-independent caspase-11-dependent inflammasome also remain to be identified. As this pathway is independent of flagellin sensing, NLRP3, ASC, and NLRC4, an unknown upstream sensor and/or adaptor may be involved in caspase-11 activation in response to a translocated bacterial substrate or an endogenous signal induced by infection. This sensor may also be upregulated by type I IFN signaling itself [27–29].

Our data show that IL-1α release during L. pneumophila infection is controlled by two independent pathways, one involving the flagellin-dependent NAIP5/NLRC4 and caspase-1-dependent inflammasome and a second pathway involving the NLRP3-independent caspase-11-dependent inflammasome (Figure 8). Though we demonstrate that IL-1α release has an important biological consequence in vivo for neutrophil recruitment and bacterial clearance, it is unclear if IL-1α release is regulated by unconventional secretion, as is the case for IL-1β [78]. As both pathways that control IL-1α release also lead to cell death, our
data are consistent with a model in which IL-1α is an endogenous alarin that is released during cell death [79].

Interestingly, caspase-11 also contributes to control of flagellin-expressing *L. pneumophila* by serving as a component of an NLR4-dependent inflammasome that promotes trafficking of the *L. pneumophila*-containing vacuole to lysosomes [80]. Thus, caspase-11 may function in multiple ways to control *L. pneumophila* infection. Importantly, we find that IL-1α, IL-1β, and IL-1R signaling play an important role in the control of *L. pneumophila* infection through efficient neutrophil recruitment to the airway. IL-1α and IL-1β play both distinct and overlapping roles in mediating neutrophil recruitment and controlling bacterial replication, as depletion of IL-1α alone showed a more pronounced defect in neutrophil recruitment and bacterial clearance than depletion of IL-1β alone, but loss of both cytokines resulted in a further reduction of neutrophil recruitment and an increased defect in bacterial clearance. Further analysis is required to define the relative contributions of the various caspase-11-mediated effector functions to the control of *L. pneumophila* replication in vivo.

In conclusion, these studies demonstrate that T3SS and T4SS activities trigger rapid and robust activation of caspase-11. This activation contributes to maximal NLRP3-dependent IL-1β secretion as well as to NLRP3-independent IL-1α release and host cell death. The downstream effector functions of these pathways are important for host defense against *L. pneumophila* in vivo, as IL-1α and IL-1β promote neutrophil recruitment to *L. pneumophila*-infected lungs and control pulmonary bacterial replication. Our results highlight the contribution of caspase-11 to rapid inflammasome activation and discrimination between pathogenic and nonpathogenic bacteria.

**Materials and Methods**

**Ethics statement**

This study was carried out in strict accordance as defined in the federal regulations set forth in the Animal Welfare Act (AWA), the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health, and the guidelines of the University of Pennsylvania Institutional Animal Use and Care Committee. The protocols were approved by the Institutional Animal Care and Use Committee at the University of Pennsylvania (protocols #803465 and #803459).

**Bacterial strains**

*Legionella pneumophila* serogroup 1 strains were used in all experiments. Macrophages were infected with Lp02 (*lxyC*), a thymidine auxotroph derived from strain Lp01 [40], or ΔlfaI [81] and ΔlfaI ΔlfaH [16] isogenic mutant strains. For *in vitro* studies, mice were infected with the Lp02 ΔlfaI or the JR32 [82] ΔlfaΔlfaH isogenic mutant strain where indicated. For *in vitro* and *in vivo* studies, *L. pneumophila* were cultured on charcoal yeast extract agar for 48 hours at 37°C prior to infection. *Escherichia coli* BL21 strain was cultured in LB broth for 16 hours at 37°C prior to infection. The *Yersinia pseudotuberculosis* strains used were IP2666 ΔyopH*OGJEMK* (Δ6) [58] and ΔyopB [83]. *Yersinia* were grown overnight with aeration in 2xYT broth at 26°C. The cultures were diluted into fresh 2xYT containing 20 mM sodium oxalate and 20 mM MgCl2. Bacteria were grown with aeration for 1 hour at 26°C followed by 2 hours at 37°C prior to infection.

**Mice**

*C57BL/6* mice were purchased from Jackson Laboratories. *Casp11−/−*, *CaspI11−/−* [84], *Casp11−/−* (unpublished data, T.S. and R.A.F.), *Casp11−/−* [30], *Asc−/−* [23], *NlrF4−/−* [85], *Asc−/−*, *NlrP3−/−* [86], *Iftar−/−* [87], *Ifnar−/−* [88], and *NlrP3−/−* [89] mice are all on the C57BL/6 background. *Asc−/−*, *NlrF4−/−*, and *NlrP3−/−* mice were originally generated by Millenium Pharmaceuticals and were a kind gift of Richard Flavell. Animals were maintained in accordance with the guidelines of the University of Pennsylvania Institutional Animal Use and Care Committee.

**In vivo infection studies**

8–12 week-old mice were anesthetized by intraperitoneal injection of a ketamine/xylazine/PBS solution at a dose of 100 mg/kg ketamine and 10 mg/kg xylazine. Mice were infected intranasally with 40 µl of a bacterial suspension containing 1 × 10⁶ CFU *L. pneumophila* or PBS vehicle control. For antibody neutralization experiments, mice were injected intraperitoneally with 100 µg anti-IL-1α antibody (clone ALF-161), 100 µg anti-IL-1β antibody (clone B122), 100 µg of each anti-IL-1α and anti-IL-1β antibody, or 100 µg Armenian hamster IgG1 isotype control antibody (eBioscience) 16 hours prior to intranasal infection. At the indicated timepoints after infection, mice were sacrificed, and the bronchoalveolar lavage fluid (BALF) and lungs were harvested. To determine bacterial load, the lungs were mechanically homogenized in sterile distilled H₂O and a portion of the lysate was spread onto CYE plates. Animal experiments were performed in accordance with approved University of Pennsylvania Institutional Animal Care and Use Committee protocols and procedures.

**Macrophage experiments**

Bone marrow was collected from the femurs and tibiae of mice. Bone marrow cells were differentiated into macrophages by culturing the cells in RPMI containing 30% L929 cell supernatant and 20% FBS at 37°C in a humidified incubator. The macrophages were replated one day prior to infection in RPMI containing 15% L929 cell supernatant and 10% FBS. For experiments involving LPS-primed macrophages, macrophages in 48-well plates (2.0 × 10⁵ cells/well) were pretreated with 0.5 µg/mL LPS for 2.5 hours and either mock-infected with PBS, infected with *L. pneumophila* at an MOI = 10 for 4 hours, or treated with 2.5 mM ATP for 1 or 4 hours. For experiments performed in the absence of LPS priming, macrophages in 48-well plates (2.0 × 10⁵ cells/well) were either mock-infected with PBS, infected with *L. pneumophila* at an MOI = 10 for 16 or 20 hours, or infected with *E. coli* at an MOI = 25 for 1 hour followed by gentamycin treatment for 15 hours. To assess the involvement of caspase-1 catalytic activity, macrophages were treated with 20 µM or 40 µM of the caspase-1 inhibitor YVAD-emk (Bachem) or an equivalent volume of dimethyl sulfoxide (vehicle control) 0.5 hours prior to infection. For *L. pneumophila* and *E. coli* infections, bacteria were centrifuged down onto the macrophages at 1200 RPM for ten minutes prior to incubation. For *Y. pseudotuberculosis* infection, bacteria were washed three times with pre-warmed DMEM, added to the cells at an MOI = 20, and centrifuged down onto the macrophages at 1000 rpm for 5 min. Cells were incubated at 37°C for 1 hour post-infection followed by addition of 100 µg/mL gentamycin. Supernatants were harvested 4 hours post infection for ELISA and LDH analysis.

**Cytotoxicity assays**

Cells were infected or treated as described above, and supernatants were harvested at the indicated times post-infection. Lactate dehydrogenase (LDH) release was quantified using the LDH Cytotoxicity Assay Kit (Clontech) according to the manufacturer’s instructions.
Immunoblotting
Supernatants from infected cells were mixed 1:1 with 2X SDS-PAGE sample buffer or infected BMDMs were directly lysed in 1X SDS-PAGE sample buffer. Samples were boiled, separated by SDS-PAGE, and transferred to Immobilon P membranes (Millipore). Primary antibodies against caspase-1 p10 (Santa Cruz Biotechnology), caspase-11 (Signa, clone 17D9), IL-1β (R&D systems), and β-actin (Sigma) were used. Detection was performed with HRP-conjugated anti-rabbit IgG (Cell Signaling Technology) or anti-rat IgG (Santa Cruz Biotechnology) or Jackson Immuno.

ELISA
Harvested supernatants from infected macrophages or the BALF from infected mice were assayed using capture and detection antibodies specific for IL-1β (pro-IL-1β) and active caspase-11 (casp11 p26) in the supernatants, and pro-casp-11 and β-actin (loading control) in the cell lysates were determined by immunoblot analysis.

Flow cytometry
To determine neutrophil recruitment to the airway, BALF cells were stained with Live/Dead Fixable Dead Cell Stain (Invitrogen), and antibodies specific for CD45 (BD Biosciences) and post-collection data was analyzed using FlowJo (Treestar). Cells were gated on singlets and live cells. Neutrophils were identified as being CD45+ Gr-1+ and Ly6G+.

Statistical analysis
Plotting of data and statistical analysis were performed using Graphpad Prism software, and statistical significance was determined by the unpaired two-tailed Student’s t test, one-way ANOVA with Tukey post-test, or two-way ANOVA with independent t test, or Dant with cell death.

Supporting Information
Figure S1 Caspase-1/caspase-11-deficient cells do not have a gross defect in cytokine secretion. A) Unprimed B6 or Casp1−/− Casp11−/− BMDMs were infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 20 hours. Levels of full-length IL-1β (pro-IL-1β) and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. B) B6 or Casp1−/− Casp11−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 4 hours. Levels of IL-12 p40 and TNF-α in the supernatants were measured by ELISA. C) Unprimed B6 or Casp1−/− Casp11−/− BMDMs were infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 20 hours. Levels of IL-12 p40 and TNF-α in the supernatants were measured by ELISA. D) B6 or Casp1−/− Casp11−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 4 hours. Levels of IL-12 p40 and TNF-α in the supernatants were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. Data are representative of two independent experiments. (TIF)

Figure S2 Caspase-11 is rapidly upregulated and secreted in response to L. pneumophila. B6 or Casp1−/− Casp11−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 4 hours. Levels of full-length caspase-11 (pro-casp-11) and active caspase-11 (casp11 p26) in the supernatants, and pro-casp-11 and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. (TIF)

Figure S3 Caspase-11 is activated in response to L. pneumophila independently of macrophage priming. (A) Unprimed B6 and Casp1−/− BMDMs or (B) B6, Casp1−/− Casp11−/−, and Casp11−/− BMDMs were infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 20 hours. Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. (C) B6, Casp1−/−, or Casp11−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 4 hours or treated with LPS+2.5 mM ATP for 1 hour. Levels of mature IL-1β in the supernatant were determined by immunoblot analysis. Data are representative of two independent experiments. (TIF)

Figure S4 IL-1α release is ASC/NLRC4-independent. B6, Casp1−/− Casp11−/−, or Asc−/− Nicf4−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) or treated with 2.5 mM ATP for 4 hours. Levels of IL-1α and IL-1β were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. Data are representative of three independent experiments. (TIF)

Figure S5 Both IL-1α and IL-1β secretion are caspase-11-dependent in vivo. 8–12 week old B6 or Casp1−/− Casp11−/− mice were infected intranasally with 1×106 ΔflaA Lp. BALF was collected 24 hours post-infection, and levels of IL-1α and IL-1β were measured by ELISA. Graphs show the mean ± SEM of three mice per group. Dashed line represents the limit of detection.* is p<0.05 by unpaired t-test. (TIF)

Figure S6 Mature IL-1β secretion is not always concordant with cell death. B6, Casp1−/− Casp11−/− Asc−/− Nicf4−/− or Asc−/− Nicf4−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp or PBS (mock infection) for 4 hours or treated with 2.5 mM ATP for 1 hour. (A) Levels of mature IL-1β in the supernatants, and full-length IL-1β (pro-IL-1β) and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. Data are representative of two independent experiments. (B) The level of IL-18 in the supernatants was measured by ELISA. Graphs show the mean ± SEM of triplicate wells. (TIF)

Figure S7 Flagellin-independent, NLRP3-dependent IL-1β secretion occurs independently of macrophage priming. (A) Unprimed B6 or Nlrc3−/− BMDMs were infected with WT L. pneumophila (Lp), ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 16 hours. Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. (B) B6 or Nlrc3−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp or PBS (mock infection) or treated with 2.5 mM ATP for 4 hours. The level of IL-18 in the supernatants was measured by ELISA. (C) B6 or Nlrc3−/− BMDMs were infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 16 hours. The level of IL-18 in the supernatants was measured by ELISA. (D) and (E) B6 BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp or PBS (mock infection) or treated with 2.5 mM ATP for 4 hours. Where indicated, media alone,
50 mM KCl, or 50 mM NaCl were added prior to infection. (D) Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. (E) Cell death was measured by LDH release. Graphs show the mean ± SEM of triplicate wells. Data are representative of two independent experiments (A–C).

**Figure S8** TRIF/IFNAR-independent IL-1 release occurs with Pam3CSK4-primed macrophages. (A) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.4 μg/mL Pam3CSK4 for 4 hours and infected with WT *L. pneumophila* (Lp), ΔdotA Lp, ΔflaA Lp, E. coli, or PBS (mock infection) for 16 hours. The levels of IL-1α and IL-1β in the supernatants were measured by ELISA. (B) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.4 μg/mL Pam3CSK4 for 4 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 16 hours. Cell death (% cytotoxicity) was measured by LDH release. (C) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 4 hours. Cell death was measured by LDH release. (D) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 4 hours. Levels of IL-1α and IL-1β in the supernatants were measured by ELISA. Graphs show the mean ± SEM of triplicate wells. Data are representative of two independent experiments. (TIF)

**Figure S9** Caspase-11 is upregulated and secreted in an IFNAR- and TRIF-independent manner. Unprimed B6, Ifnar−/−, or Trif−/− BMDMs were infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS for 16 hours. Levels of full-length caspase-11 (pro-casp-11) and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. (TIF)

**Figure S10** Detection of caspase-11 protein upregulation in cell lysates is moderate in response to *L. pneumophila*. (A) Unprimed B6, Ifnar−/−, or Trif−/− BMDMs were infected with WT Lp, ΔdotA Lp, ΔflaA Lp, E. coli, or PBS (mock infection) for 16 hours. (B) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.4 μg/mL Pam3CSK4 for 4 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, E. coli, or PBS for 16 hours. (C) B6, Ifnar−/−, or Trif−/− BMDMs were primed with 0.5 μg/mL LPS for 2.5 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, E. coli, or PBS for 4 hours. Levels of full-length caspase-11 (pro-casp-11) and β-actin (loading control) in the cell lysates were determined by immunoblot analysis. (TIF)

**Figure S11** Caspase-11 is not upregulated in the absence of both MyD88 and Trif. (A) Immortalized B6 (B6) or MyD88/Trif-deficient (Myd88−/−Trif−/−) BMDMs were primed with 0.4 μg/mL Pam3CSK4 for 4 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, E. coli, or PBS (mock infection) for 16 hours. B: IFN-α or IFN-β/Trif−/− BMDMs were primed with 0.5 μg/mL LPS for 4 hours and infected with WT Lp, ΔdotA Lp, ΔflaA Lp, or PBS (mock infection) for 4 hours. Levels of full-length caspase-11 (pro-casp-11) and β-actin (loading control) were determined by immunoblot analysis. (TIF)

**Figure S12** Caspase-11-deficient cells secrete comparable amounts of IL-12 in response to *Y. pseudotuberculosis*. B6, Casp1−/−, Casp11−/−, Casp1−/−, or Casp11−/− mice were primed with 0.05 μg/mL LPS for 2.5 hours and infected with type III secretion system-deficient *Y. pseudotuberculosis* (ΔyopB Yp), effectors *Y. pseudotuberculosis* ΔH0JimE (Δ6 Yp), or PBS (mock infection) or treated with 2.5 mm ATP for 4 hours. The level of IL-12 p40 in the supernatants was measured by ELISA. Graphs show the mean ± SEM of triplicate wells. Data are representative of two independent experiments. (TIF)

**Figure S13** Intraperitoneally injected antibodies neutralize cytokine in the BALF. 8–12 week old B6 mice were injected intraperitoneally (IP) with either PBS, 100 μg anti-IL-1α antibody, 100 μg anti-IL-1β antibody, or 100 μg each of anti-IL-1α and anti-IL-1β (anti-IL-1α/β) 16 hours before infection. The mice were then infected with either 1×10⁶ ΔflaA Lp or mock infected with PBS intranasally (IN). 24 hours post-infection, bronchoalveolar lavage fluid (BALF) was collected and the levels of IL-1α and IL-1β were measured by ELISA. Labels indicate what was received intraperitoneally (IP) and what was received intranasally (IN). Graphs show the mean ± SEM of 8 mice per group and represent the pooled results of two independent experiments. (TIF)

**Acknowledgments**

We are grateful to Junying Yuan (Harvard University) for permission to utilize Casp11−/− mice, Tiffany Horng (Harvard University School of Public Health) for providing Casp11−/− bone marrow, and Susan Weiss (University of Pennsylvania Perelman School of Medicine) for providing Fltn−/− bone marrow. We also thank the Brodsky lab for valuable feedback on experimental design.

**Author Contributions**

Conceived and designed the experiments: CNC AMC EEZ IEB SS. Performed the experiments: CNC AMC EEZ HTN BJ IEB SS. Analyzed the data: CNC AMC EEZ HTN BJ IEB SS. Contributed reagents/materials/analysis tools: TS RAF IEB SS. Wrote the paper: CNC IEB SS.
