Abstract

Objective

Thyroid autoimmunity (TAI) per se has been demonstrated to be related to adverse pregnancy outcomes, including recurrent miscarriage and unexplained infertility. Although therapy of glucocorticoid to infertile remains controversial, aspirin combined with prednisone (P + A) are used frequently in antithyroid antibodies (ATA) positive infertile women in clinical practice.

Methods

A multicenter retrospective study was performed in the Second Affiliated Hospital of Zhejiang University School of Medicine, Ningbo Women and Children's Hospital and People's Hospital of Jinhua. We recruited 494 euthyroid infertile women positive for anti-thyroidperoxidase antibody (TPOAb) and/or thyroglobulin antibody (TgAb) with thyroid stimulating hormone 0.35-4.0mIU/L, who undergoing first in vitro fertilization and embryo transfer (IVF-ET) cycle during the period of 2017 to 2020. 346 women were ultimately recruited, including 187 patients receiving fresh embryo transfer and 159 patients receiving frozen-thawed embryo transfer. Among them, infertile 150 women were treated with prednisone (10mg/d) and aspirin (100mg/d), while the other 196 infertile women were untreated as control group. The treatment commenced on the day of embryo transfer and continued until the clinical pregnancy was determined by ultrasonography around 30 days after embryo transfer.

Results

Clinical pregnancy rate (CPR) of the first fresh embryo transfer cycle was 57.5% vs. 63.5% in control vs. in treated group (P = 0.414) and CPR was 57.8% versus 61.8% in the two groups in the frozen-thawed embryo transfer cycle (P = 0.606). Additionally, the prevalence of delivering a live birth at the fresh embryo transfer was 49.6% in the non-treatment group and 47.3% in the P + A treated group (P = 0.762). Cumulative CPR was similar in the groups at the fresh embryo transfer (control vs treated group: 56.9% vs 61.0%, P = 0.534). By conducting logistic regression, combined treatment of P + A appeared to have no influence on CPR or miscarriage rates (MR) at the first embryo transfer. Furthermore, the low but within the reference level of free triiodothyronine (FT3) was seen as a poor predictor of spontaneous abortion at the fresh embryo transfer.

Conclusions

To conclude, with regard to euthyroid women with TAI undergoing the first IVF-ET cycle, adjuvant treatment of P + A after the embryo transfer may be unnecessary irrespective of the fresh or frozen-thawed embryo transfer.

Introduction

In spite of numerous advances in the assisted reproductive technology (ART), such as controlled ovarian stimulation, assisted hatching and pre-implantation genetic testing, implantation remains a long-standing and rate-limiting step in the IVF treatment[1]. To the best of our knowledge, to attain a successful implantation relies on the intricate collaboration of good-quality embryos with receptive human endometrium, both of which are indispensable[2–4]. Therefore, when good-quality embryos or even euploid embryos are prepared for the transfer, the endometrium may be responsible for the implantation failure[4, 5]. The major factors that establish uterine receptivity for implantation and further embryo development are progesterone, estrogens and the immunological system[6]. In addition, the reprogramming process of the maternal immune system from rejection to temporary tolerance towards the fetal (paternally derived) semi-allograft depends on the well-designed endocrine-immune interaction[7–9]. Generally speaking, normal female immune system usually induces tolerance toward the embryo, whereas the tolerance induction is incomplete in a hyperactive immune system, reducing fertility and increasing the risk of miscarriage[7]. Among the various studies investigating the immunological mechanisms, thyroid autoimmunity, as a predictor of generalized autoimmune disturbance, closely connected with recurrent embryo implantation failure, early pregnancy loss and adverse pregnancy outcomes[10–12]. Furthermore, several studies revealed that ATA did not affect embryo quality, but decreased clinical pregnancy rate, partly because of the impaired maternal immune[13]. In reality, for the purpose of dealing with reproductive challenges encountered by infertile woman who are positive for ATA and desire for pregnancy, prednisone (P) for immunosuppression and aspirin (A) as an antithrombotic agent are prescribed frequently and customarily in clinical practice.

As a therapeutic alternative, corticosteroid hormones in combination with aspirin probably pose a potential benefit on improving blood perfusion to the ovaries and endometrium, lowering the local inflammatory reaction to the transfer procedure, thus inducing a more favorable micro-environment for the transferred embryo[14, 15]. However, insufficient evidence existed to determine whether aspirin and prednisone therapy improve the likelihood of pregnancy following ART in thyroid Ab-positive euthyroid women.
Aim of the study was to evaluate whether or not the treatment of prednisone in addition to aspirin was capable of improving pregnancy outcomes of the first IVF/ICSI cycle in euthyroid infertile women only with thyroid autoimmunity antibodies positive.

Methods

2.1 Patients

We conducted a multicenter retrospective study involving 494 infertile women who tested positive for TPOAb and/or TgAb and were being treated for infertility at the Second Affiliated Hospital of Zhejiang University School of Medicine, Ningbo Women and Children's Hospital and People's Hospital of Jinhua from October 2017 to July 2020. Both TPOAb and TgAb in all the subjects were measured before ART procedure, and their thyroid stimulating hormone (TSH) level ranged from 0.35-4.0IU/L and also, they all underwent first embryo transfer without previous IVF history. That is to say, we screened and involved only first-time ART users and analyzed only first embryo transfer (fresh or frozen-thawed embryo transfer) and first cycle. Inclusion criteria were age of less than 40 years, regular (21-35days) spontaneous menstrual cycle, normal uterine cavity, presence of both ovaries, and normal ovarian reserve as defined by basic follicle stimulating hormone(bFSH) < 10 IU/L and antral follicle count (AFC) no less than 5.

Women with known autoimmune diseases or clinical presentations of autoimmune disorders including systemic lupus erythematosus (SLE), antiphospholipid syndrome (APS) (n = 2), in whom thyroid function test were not normal(n = 38), who were diagnosed with diseases affecting the uterine cavity (n = 12), and those infertility caused by severe oligoasthenospermia and azoospermatism (n = 16) were excluded. Equally, 8 women or their partners with aberrant chromosome karyotype particularly significant parental balanced translocations or Tumor mosaicism were ruled out. One woman was excluded due to medical history of insulin-dependent diabetes mellitus (DM), 7 women due to no mature oocyte to retrieve and 64 women on account of receiving no embryo transfer for various reasons.

Of the remaining ATA (+) women, 187 women achieved fresh embryo transfer and 159 women fulfilled frozen-thawed embryo transfer, 150 (43.4%) patients received P + A treatment during ART(Fig. 1). The study was reviewed and approved by the Ethics Committee of the Second Affiliated Hospital of Zhejiang University School of Medicine, Ningbo Women and Children's Hospital and People's Hospital of Jinhua.

2.2 Laboratory assays

Women's serum samples were analyzed by the standard third-generation electrochemiluminescence (ECL) immunoassay (CobasElesys 601, Roche) in the three reproductive centers. Thyroid autoimmunity (TAI) was defined as the presence of serum antibodies directed against TPO and/or TG. The reference range was 0–5.61 IU/mL for TPOAb and < 4.11 IU/mL for TgAb. TPOAb titers of more than 5.61 IU/mL and/or TgAb values exceeding 4.11 IU/mL were considered ATA-positive. Women were diagnosed with euthyroidism when serum levels of TSH were within the reference of 0.35-4.0mIU/L and none of the free thyroxine (FT4) or triiodothyronine (FT3) was outside their reference ranges. The reference values were 0.7-1.48ng/dL for FT4 and 1.71-3.71pg/mL for FT3. These reference values were given by the company producing these assay kits.

2.3 ART procedure and collection of clinical information

All patients underwent ovulation induction with recombinant follicle-stimulating hormone (rFSH) (Gonal F; Serono, Switzerland) or human menopausal gonadotropin (hMG) (Livzon, China) to obtain a cohort of mature oocytes at the time of oocyte retrieval. Pituitary inhibition was achieved by a gonadotropin-releasing hormone (GnRH) analog (Decapeptyl; Ferring, Switzerland) or GnRH antagonist (Centrotide; Serono, Germany). The doses of these drugs were adjusted according to the women's age and the number of antral follicles and day three serum FSH values. Cycle monitoring was carried out using transvaginal sonography plus laboratory assays. As soon as a minimal of three leading follicles reaching 17 to 18 mm paired with appropriate serum E2 levels, 5000–10,000 IU of human chorionic gonadotropin (hCG) (Livzon, China) was administered. Therefore, by virtue of the guiding of transvaginal ultrasound, cumulus oocyte complexes (COCs) were aspirated 36 to 38 hours after hCG injection. Subsequently, whether using conventional IVF or ICSI was relied on the semen condition and clinical indication. The previous history of obtaining poor-quality oocytes, recurrent fertilization failure with IVF technique and high titers of anti-sperm antibodies favored ICSI. Under the condition of tubal factor or unexplained infertility, and ovulation failure with all possible conventional methods, the IVF procedure was employed.[16]. On day 2 and 3 after oocyte collection, embryos were assessed and scored according to the number and size (even or uneven) of blastomeres, fragmentation, and multinucleation. Embryos were transferred on the third, fifth or sixth day of culture according to the age of the patient and embryo quality. All patients were transferred of the best quality embryos. According to the ART regulation published in 2018, the total number of embryos transferred per cycle shall not exceed three, including no more than two embryos for women under the age of 35 during the first cycle of assisted reproduction. In the frozen-thawed embryo transfer cycle, hormone replacement treatment with estradiol administered orally (6 mg/day) from the third day of the target cycle or natural cycle was adopted for endometrial preparation. An ultrasound examination was performed to measure and record endometrial thickness as the maximum distance (mm) between the myometrium and endometrial surface. A thickness of ≥ 7.5 mm was considered satisfactory for initiating progesterone supplementation. Luteal phase support was added in the form of micronized progesterone capsules and oral dydrogesterone starting from the day of oocyte collection in the fresh embryo transfer
cycle and continued until the day of the pregnancy test. When the patient was pregnant, the supplement was continued during the first pregnancy trimester. Fourteen days after ET, serum hCG was assessed for the confirmation of biochemical pregnancy and clinical pregnancy was determined by ultrasonography to visualize an intrauterine gestational sac, which was performed 5 weeks after ET. The following clinical data including women's age, body mass index (BMI), duration of infertility, previous history of miscarriage, bFSH, anti-Mullerian hormone (AMH), antral follicle count (AFC) were recorded and analyzed. Laboratory parameters and pregnancy outcomes were also documented: total gonadotropin (Gn) doses, days of Gn treatment, E2 levels on hCG day, endometrial thicknesses on hCG day and embryo transfer day, oocytes retrieved, fertilization rate, number of embryos for transferring, implantation rate of cleavage and blastocyst stage embryos, pregnancy rate (PR), clinical pregnancy rate (CPR), miscarriage rate (MR), live birth rate (LBR) and cumulative rate.

2.4 Adjuvant medical treatments

Overall, a total of 346 euthyroid infertile women with TAI were divided into two groups, the control group involving 196 patients as well as prednisone (Xianju pharmaceutical factory, China) plus aspirin (Bayer, Germany) (P + A) treated group consisting of 150 women. As illustrated in Fig. 1, 187 women acquired fresh embryo transfer and of them 74 (39.6%) received P + A adjuvant medicine. Among 159 frozen-thawed embryo transfer, 76 (47.8%) were supplied with prednisone plus aspirin. In the treatment group, a daily dose of 100mg orally administered aspirin (A) and 10mg prednisone (P) started from the day of ET and continued until the time of hCG test. The positive hCG test indicated ceaseless medication and drug stopped at the time when successfully clinical pregnancy was established. Treatment was also discontinued if persistent hCG decline occurred.

2.5 Outcome measures

Primary outcome was clinical pregnancy rate (CPR) after the first embryo transfer. Secondary outcomes were implantation rate of cleavage stage embryos, miscarriage rate (MR) and live birth rate (LBR) after the first embryo transfer. Besides, cumulative pregnancy rate, clinical pregnancy rate as well as live birth rate were also reported.

Pregnancy rate was the percentage of transfers with positive serum level of beta-hCG (≥ 5 mIU/mL). Clinical pregnancy was defined as the existence of a viable embryo within an intrauterine gestational sac. Spontaneous abortion rate was defined as the ratio between the number of pregnancy loss after sonographic visualization of an intrauterine gestational sac and the number of clinical pregnancies. Recurrent miscarriage (RM) is defined by the loss of two or more clinical pregnancies. Implantation rate was calculated as the number of sacs with fetal heart beat divided by the total number of embryos transferred. Live birth rate was the percentage of transfers resulting in a live birth. Cumulative rate was calculated as soon as the first IVF cycle was completed or patients without delivering a live birth were followed up to 1 years after the first embryo transfer when the first IVF cycle was not completed. A complete cycle was characterized as all transfer cycles in an IVF cycle started with oocyte stimulation, ended with live birth or no available embryos or abandonment.

2.6 Statistics

Data analysis was performed using the Statistics Package for Social Sciences (SPSS 24.0). First, a Kolmogorov-Smirnov test was applied to both groups and variables to evaluate whether the distribution was symmetrical or not. Continuous data were expressed as median (25th-75th) when not normally distributed, and as mean ± SD for normally distributed data. Categorical data were calculated as numbers (percentage) of cases. Comparisons of quantitative data were analyzed by the Mann-Whitney U test or independent T test on the basis of distribution status and Chi-square or two-sided Fisher’s exact test was deployed in categorical data.

For the logistic regression analysis, the independent variables were age and FT3 levels in the whole range. CPR and MR were considered as dependent outcomes.

The significance level of alpha was defined as 0.05. And a value of p < 0.05 was considered statistically significant.

Results

3.1 Clinical characteristics

Characteristics of women with positive antithyroid antibodies were shown in Table 1. Obviously, the clinical descriptive characteristics were broadly comparable between P + A treated group and non-treated group, which consisted of age, BMI, number of previous miscarriages, duration of infertility, the proportion of primary infertility, bFSH, AMH, AFC, TSH, FT4, the ratio of only TPOAb positivity, only TgAb positivity, or TPOAb and TgAb positivity. Furthermore, the cause of infertility was comparable between those groups (Supplemental Table SI). Firstly, we turned to the fresh embryo transfer cycles. In women of treated group, the median age of the women was 31.0 (29.0–35.0) years old and the majority was within the range of 31–37 years old, the data similar to the control group. For these two groups, the overweight and obesity patients accounted for 22.0% (control group) and 22.3% (P + A group), respectively (P = 0.336). The prevalence of women with recurrent abortion was 20.3% in the P
3.6 Comparison of IVF outcomes of continuous embryo transfers controlled trials, to assess the value of the additional treatment in RPL women with thyroid autoimmunity.

Outcome on account of its small sample size. It definitely required caution to illustrate and further investigations, preferably randomized.

3.5 Recurrent pregnancy loss and IVF outcome

Baseline demographics and clinical characteristics were comparable between groups (Supplemental Table SII). Based on our analysis, there was an absence of association between treatment with P + A and subsequent pregnancy outcomes in women suffering for unexplained recurrent pregnancy loss (RPL) who had autoimmune thyroid disease (Supplemental Table SIII). However, the study was not adequately powered for this outcome on account of its small sample size. It definitely required caution to illustrate and further investigations, preferably randomized controlled trials, to assess the value of the additional treatment in RPL women with thyroid autoimmunity.

3.4 Logistic regression analysis

Since there was a significant difference in FT3 at the fresh embryo transfer cycle between women with or without P + A treatment, we performed a multiple logistic regression analysis and also took, the clinically relevant variable, into account (Table 4). In women transferred with fresh embryos, after adjusting for age and additional treatment, significantly, FT3 within the normal reference appeared to have a negative relationship with miscarriage rate (odds ratio [OR] 0.248 [95% confidence interval, CI 0.063–0.984], P = 0.047). Furthermore, P plus A treatment was presented to exert no influence on miscarriage rate or clinical pregnancy rate.
The comparison of IVF outcomes of continuous embryo transfers in women receiving nothing at the first embryo transfer but obtaining therapy at the additional frozen embryo transfers was depicted in Supplemental Table SIV. In other words, this part was before-after study in the same patients. As shown in the Supplemental Table SV, the presence of prednisone and aspirin seemed to be not of benefit to final reproductive outcomes. Nevertheless, there existed obvious shortcomings of limited eligible evidence, discrepant ratio of cleavage stage embryo to blastocyst stage embryo and various type of embryos transferred, fresh or frozen-thawed, implying an inevitably questionable conclusion.

**Discussion**

The correlation between antithyroid antibodies, fecundity and pregnancy outcome is quite debatable and conflicting. Previously, meta-analysis of 4 prospective studies that included 1098 subfertile women undergoing IVF noted a significant two fold higher risk of miscarriage of subfertile euthyroid women with TAI compared with a counterpart without TAI[17]. Among those four prospective studies, three of them only measured TPO-Ab, one study recruited participants with unexplained infertility and no history of miscarriage, subfertile women with various etiology and normal thyroid function was reported in another two prospective investigations and the last one specifically excluded women with a history of miscarriage. Under the circumstances of different ART/IVF protocols employed, dissimilar underlying etiologies contributing to infertility and changeable cut-off values concerning euthyroidism and subclinical hypothyroidism, the 2017 American Thyroid Association (ATA) pregnancy guidelines was not able to come to a definite conclusion on the link between thyroid autoimmunity and ART outcomes. What's more, levothyroxine treatment was recommended for subclinical hypothyroidism, defined as a TSH > 2.5 mIU/L, and considered for euthyroid infertile women with thyroid autoimmunity when they attempted to conceive by virtue of assisted reproductive technologies in the 2017 ATA guidelines after weighing the pros and cons of levothyroxine supplement[18].

However, in the past few years following the publication of the 2017 ATA guidelines, two large randomized controlled trials(RCT) assessing the value of levothyroxine on pregnancy outcomes in euthyroid TPO-Ab positive women reported that the use of levothyroxine was not associated with improvements on miscarriage and live birth rate[19, 20]. Though there existed several limitations involving fixed levothyroxine doses, undetermined TSH values during early trimester of pregnancy following medicine supplement, uncertain population compliance and the exclusion of women with recurrent miscarriages or positive for other autoimmune antibodies, the large-sample RCT results were essential and provoking on levothyroxine effectiveness in the specific euthyroid women with thyroid autoimmunity[21]. Furthermore, a recent meta-analysis of six RCTs demonstrated that levothyroxine had no capacity to improve clinical pregnancy outcomes among women positive for thyroid peroxidase antibody. As a matter of fact, of the meta-analysis based on high- to moderate-quality evidence, two trials underwent ART, two studies used fixed levothyroxine doses and one investigation enrolled euthyroid or subclinical women[22]. Thus, further large-scale high-quality investigations on specific population are still urgently needed.

On account of decreased effectiveness of levothyroxine and generalized autoimmune imbalance resulted from thyroid autoimmunity, we retrospectively explored the power of aspirin plus prednisone treatment on euthyroid women with TAI undergoing their first IVF/ICSI procedure. Markedly, there exists a robust, dynamic and responsive immune system for a successful pregnancy. Pregnancy begins in a pro-inflammatory stage allowing implantation and placentation, then shifts to an anti-inflammatory environment which is pivotal for fetal growth, and finally come back to a pro-inflammatory stage available to labor and delivery. A pro-inflammatory process is initiated in the embryo implantation and trophoblast invasion to better promote cell clearance, angiogenesis, cell growth and tolerance, as the pro-inflammatory procedure is characterized by the presence of angiogenic factors, growth and survival factors, and cytokines and chemokines[23]. Following implantation, the female immune system usually induces tolerance towards the embryo, whereas tolerance induction is incomplete in a hyperactive immune system. Subfertile women with autoimmune thyroid disease usually expressed increased level of INFy from pro-inflammatory Th1 immune cell and reduced secretion of IL-4 and IL-10 from Th2 immune cell compared to controls with no anti-thyroid antibodies, suggesting that the excessive activated pro-inflammatory Th1 cell hampered the subsequent successful pregnancy[24]. Moreover, pinopodes, the spherical protrusions of the epithelial plasma membrane into the lumen, are characterized as classic morphological biomarkers of receptive endometrium favoring implantation. Recently and firstly, a euthyroid Hashimoto’s thyroiditis (HT) mice model was established and explored the correlation of HT and endometrial receptivity defects, indicating that HT alone inhibited luminal epithelium development, retarded the formation and development of pinopodes, decreased expression of receptivity markers, thereby inducing a nonreceptive endometrial milieu and leading to implantation failure[25]. Prednisone, a type of glucocorticoid, is readily absorbed from the gastrointestinal tract and used primarily for its anti-inflammatory effects in many system disorders[26]. A substantial amount of trials revealed that low doses of corticosteroids (10 mg/day) had improved the IVF pregnancy outcome in women experiencing immunological infertility and recurrent miscarriages, even with a prior history of 19 consecutive miscarriages[27–30]. Moreover, by virtue of cleavage stage mouse embryos exposing to 3 and 30 µM concentrations of prednisolone(PRLD) in vitro to mimic the possible clinical scenario and to assess the embryonic response to direct PRLD exposure, a recent animal study revealed that exposure to 30 µM PRLD delayed the embryonic progression, decreased hatching potential and increased apoptosis in blastocysts, and yet, 3 µM PRLD exposure increased inner cell mass (ICM) proliferation ability which was incorporated to predict the implantation potential[31]. It was worth mentioning that 3 µM was close to the therapeutic dose and 30 µM to reflect the ten-times higher than the initial level. Experimental evidences in animal models implied that glucocorticoids at higher concentrations could negatively affect oocyte maturation and early embryogenesis. The therapeutic dose of PRLD had the capacity to reduce post-implantation demise, possibly due to its
stimulus on choriocarcinoma cell lines. Similarly, the latest trial to investigate the role of prednisolone on deciduization and decidual-trophoblast interactions reported that prednisolone treatment enhanced trophoblast outgrowth, elevated trophoblast mRNA expression of cell motility gene PLCG1, altered decidual-trophoblast interactions and yet the clinical consequences of these changes were unknown[32]. Thus, there remains a great need for further research on this topic. On the other side, with the capacity to decrease blood viscosity and increase blood flow, which is secondary to the inhibition of cyclooxygenase-1 and decreased production of thromboxane-2, low dose of aspirin plays an essential role in improving uterine and ovarian blood flow, enhancing embryo implantation and sustaining early pregnancy. Besides, daily low-dose aspirin use is considerably safe as it did not contribute to any changes to menstrual cycle, follicular phase, or luteal phase length or hormone levels across the menstrual cycle[33]. The adjuvant treatment of aspirin in combination with prednisone is recommended to patients with autoantibodies undergoing IVF as its benefits are demonstrated in several investigations[27, 28, 34]. However, these trials are published from a long time ago and don’t reveal the efficacy of medicine on infertile women who present positive only for antithyroid antibodies.

In our study, we applied ranges of < 31 years, 31–37 years, and > 37 years according to the physiological understanding of natural fertility, whose initial decline began at 31 years and the critical age of 37 years recorded as the pivotal age for success rates in treatment programs[35, 36]. Notably, the rough distribution of age was comparable and thus reduced the potential confounding risk of age, as advanced age predisposed to induce increased chance of de novo chromosomal aberrations in oocytes, and, in turn, in the embryo[11, 37, 38]. With regard to ovarian reserve, age, AMH, AFC and bFSH were comparable between women administrated with medicine or not at both fresh and frozen embryo transfer cycles. Additionally, significant parental chromosome abnormality, severe oligoasthenospermia and azoospermia were definitely excluded in our study as the rate of chromosomal anomaly was 0.24% in normal semen group, 4.7% in moderate-to-severe oligoasthenospermia group and 9.59% in azoospermia group[39]. The consistency between two groups provided confidence for us to come to the final conclusion as 30–50% of implantation failures can be attributed to poor embryo quality and the embryo quality is determined by a number of parameters primarily of the woman’s age, ovarian reserve, the underlying causes of infertility and sperm quality. In addition, decreased endometrial receptivity is thought to account for similarly two thirds of these failures[5]. Typically, endometrium is the direct or indirect target of antithyroid antibodies, prednisone and aspirin.

In the context of the unclear and indefinite efficacy of both antibodies, we recorded and analyzed the proportion of positive isolated TPOAb, positive isolated TgAb, and double positive TPOAb and TgAb in our study and no significant difference was observed. Moreover, in our study, euthyroidism was defined as the reference value of 0.35-4.0 mIU/L for the TSH and the value was comparable between two groups. The borderline of euthyroid and subclinical hypothyroidism is changeable over time. Nowadays, the association between elevated maternal TSH concentrations and pregnancy-specific complications appears to be more pronounced when adopting the cut-off point of 4.0 mIU/L, or a population-based reference value than the level of 2.5 mIU/L[40]. And newer guidelines suggested that an upper limit of 4.0 mIU/L should be considered diagnostic compared with the previous guideline of 2.5 mIU/L[18]. Based on the borderline of 4.0 mIU/L for the TSH and 2017 ATA recommendations, levothyroxine supplement was not included in our study.

Interestingly, we observed no association between prednisone plus aspirin treatment and reproductive outcomes including CPR, MR and LBR at the first embryo transfer regardless of fresh or frozen embryo transfer. Selected and assessed infertile women owned normal thyroid test and no autoimmune antibodies except anti-thyroid antibodies. This finding had not been replicated in other literature and should be interpreted with caution. In 2009, Alberto Revelli et al performed a retrospective study of 329 euthyroid women who were positive for TPOAb, TgAb, or both. The medication was prednisolone (10 mg/d) and aspirin (100 mg/d) from the day of stimulation to 10 weeks of gestational age, and during that period, P was increased to 30 mg/d for 5 days starting from the day of ET. Such a medication approach was acknowledged as of value on pregnancy and implantation rates in contrast with untreated ATA + patients[34]. The timing of medication in our study commenced on the day of embryo transfer and lasted for 2–6 weeks, mainly focusing on fascinating the implantation micro-immune environment. In a prospective case-control study including 233 consecutive patients, dexamethasone (0.5 mg/d) and acetylsalicylic acid (100 mg/d) starting from the day of embryo transfer and continuing until the end of the 12th week of gestation increased the pregnancy rate and implantation rate when compared with the control group[42]. But it was noteworthy that the inclusion of this prospective study was inherited and acquired thrombophilia, compound heterozygous polymorphisms, positive anti-nuclear and anti-thyroglobulin antibodies, the strong indication for steroid hormone and anticoagulant drug[42]. Coincidentally, its inclusion standard was exactly in line with the exclusion criteria in our study, which largely explained the conflicting results. Thus, the effective value of treatment may not be obvious in women with unaffected thyroid function and only thyroid antibodies when compared with those with multiple types of autoantibodies or the history of RPL.

When talking about the mixed correlation between TAI and infertility, a recent review published in 2020 may help us to have a better understanding of its relevance. By summarizing and analyzing the latest studies since the 2017 guidelines, the review documented that anti-TPO Abs were associated with infertility in subsets of women mainly with unexplained infertility or polycystic ovarian syndrome (PCOS), but not all women[21]. Such a conclusion was primarily dependent on a secondary analysis of data from two multicenter RCTs involving 1650 euthyroid infertile women either with unexplained infertility or PCOS[41]. The weak correlation of TAI and IVF reproductive outcomes of general infertile population possibly partially explained the negative results of our study. Furthermore, a 2020 meta-analysis of seventeen studies pinpointed a statistically significant association between RPL and TAI (odds ratio 1.94; 95% CI, 1.43–2.64) and the statistical significance and magnitude of
the results remained unchanged following sensitivity analyses[43], similar to the finding of our previous investigation[44]. As for euthyroid infertile women with unexplained infertility, PCOS or RPL, little evidence existed concerning the effect of replacement therapy of A plus P in those specific women. Besides, owing to the paucity of a great number of subjects, stratified research is usually not likely to fulfill at the subgroup level. However, based on the fact that P plus A treatment did play a positive role on improving adverse IVF reproductive outcomes in women with positive antinuclear antibodies[45], with unexplained RPL[46] and with other immune-related antibodies[15]. Combined treatment is likely to exert great influence on euthyroid infertile women with TAI and unexplained infertility or RPL, though it still requires prospective large-sample trials to justify its potency.

Additionally, in our study, there existed a phenomenon that no matter what type of embryo transferred, a higher but not significant incidence of abortion occurred in the treated group. As illustrated above, the value of FT3 in the P + A treated group was 2.90 ± 0.39 pg/mL, significantly lower than that of ATA-positive untreated subjects(P = 0.017). Multivariable logistic regression demonstrated the negative role of FT3 played on the incidence of fetus loss at the first fresh embryo transfer. The demonstration was buttressed by a preliminary observational study, which reported that low serum FT3 level compromised the beneficial effect of levothyroxine substitution in women with Hashimoto thyroiditis[47]. It is widely acknowledged that thyroid hormone transportsers, receptors and their associated proteins are expressed in the ovary, the early embryo, endometrium, uterus and placenta[7]. Thus, optimal value of T3 is crucial for ovulation and folliculogenesis as T3 in combination with FSH appears to enhance granulosa cell proliferation and inhibit granulosa cell apoptosis via the PI3K/Akt pathway[7, 16]. Simultaneously, the expression of these proteins in the endometrium is changeable throughout the various phases of the menstrual cycle[48]. It's documented that receptive endometrium is accompanied with strengthened expression of thyroid hormone(TH) receptors in normal women[49], whereas weakened expression of proteins concerning thyroid hormone in the uterus is observed at the day of implantation in hypothyroid pregnant rats[50]. By means of the binding of TH receptors on the placenta and endometrium, as well as regulating the invasive potential of extravillous trophoblasts, thyroid hormone is capable to affect implantation and early fetal development[7]. To conclude, the evidence and statement above seemingly suggest the provision of additional levothyroxine supplement in euthyroid infertile women with low but in the normal reference range of FT3. One potential pathogenesis model with regard to the link between thyroid autoimmunity and fertility may offer us a new perspective[21]. At early stages of autoimmunity, the main undesirable impact is through a hostile immune environment at the level of the ovary, with TPO as the direct antigen. At this stage, the thyroid hormone response is intact and the levothyroxine treatment is inefficient. As thyroid autoimmunity progresses, an impaired thyroid response to hCG stimulation appears and unable to meet the excess thyroid hormone demand under the condition of pregnancy. In that situation, treatment with thyroid hormone will be beneficial[21]. On the basis of such a new model, to distinguish the different stage is the key to efficient treatment.

Although progress has been made in some areas of the autoimmune disorders, little is known about the comprehensive understanding of the underlying mechanism of autoimmune antibodies on reproductive outcome, leading to a barrier to a deeper search of effective treatments. Organs-on-a-chip, claimed as advanced in vitro models of multicellular tissue complexes or functional organ units, may help illuminate the possible intricate connection. Exploiting organ-on-a-chip approaches to modeling decidualization, implantation and placentation, they are capable of in-depth investigating the invasive and remodeling behavior of extravillous trophoblast cells, the procedure crucial of establishing the uteroplacental circulation that provides vascular supply to the growing fetus[51]. Further to that, interaction of antibodies and endometrium, changeable expression of immunological factors as well as glucocorticoid acting point are all standing a chance of being explored.

To conclude, according to the reality of routine thyroid screening, a large number of euthyroid women who test positive for antithyroid antibodies are discovered. Among them, patients underwent the first IVF cycle without the history of recurrent miscarriages or unexplained infertility are not recommended for the combined treatment of prednisone and aspirin. As a whole, there were several advantages in our study. Firstly, by means of establishing strict inclusion and exclusion criteria, we controlled for the possible confounding factor of other autoantibodies and several severe detrimental elements of spontaneous miscarriages to minimize, as much as possible, any patient-related variation in order to concentrate on the effects of aspirin in combination with prednisone on isolated euthyroid infertile women with TAI. Secondly, we only included first-time ART users and analyzed only first cycle ART outcomes to investigate homogeneous good-prognosis population and provide relevant suggestions for targeted subjects. Additionally, our study also had some limitations. Firstly, the current study was inevitably limited by its retrospective nature. Secondly, given the variation of TPOAb and TH concentrations in the context of pregnancy, measurement of longitudinal thyroid parameters during pregnancy was appreciable and yet we did not record the change[52]. While P + A supplement did not improve live birth rate or pregnancy rate in euthyroid TAI women at the first embryo transfer, the potential benefits of P + A supplementation during pregnancy could not be ruled out. Additional randomized clinical trial is required to determine whether P + A yield different results on women who test positive for antithyroid antibodies with recurrent implantation failure or with unexplained infertility. Similarly, it is possible that a higher risk population with increased recurrent pregnancy loss might yield different results.

**Conclusion**

To conclude, according to the reality of routine thyroid screening, a large number of euthyroid women who test positive for antithyroid antibodies are discovered. Among them, patients underwent the first IVF cycle without the history of recurrent miscarriages or unexplained infertility are not
recommended for the combined treatment of prednisone and aspirin.

Declarations

Acknowledgement

The authors thank the staff of Reproductive Medicine Center of Second Affiliated Hospital of Zhejiang University School of Medicine, Ningbo Women and Children's Hospital and People's Hospital of Jinhua for sample collection.

Funding

This project was supported by the National Natural Science Foundation of China (NSFC) (81671487).

Contributions

Patient selection: P. Z and Y.Y; sample collection and processing: J. X, Q.Z and L.Y; data analysis and interpretation: P. Z and Q.Y; study design: C.F, L.Z and M.J; manuscript drafting: P. Z and M.J. All authors read and approved the final manuscript.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest regarding the publication of this article.

Ethics declarations

Ethics approval and consent to participate

All trials were performed in strict accordance with the Ethics Committee at the Second Affiliated Hospital of Zhejiang University School of Medicine. Informed consent was exempt on account of retrospective study. The Committee of the Second Affiliated Hospital of Zhejiang University School of Medicine approved the protocols (registration number: 2021-0062).

Consent for publication

All co-authors have seen and approved the final version of the paper and have agreed to its submission for publication.

Competing interests

The authors declare that they have no competing interests.

Availability of data and materials

All data generated or analyzed during this study are included in this published article and its supplementary information files.
