(Dated: February 17, 2016)

Using fully kinetic simulations, we study the suppression of asymmetric reconnection in the limit where the diamagnetic drift speed \(\gg\) Alfvén speed and the magnetic shear angle is moderate. We demonstrate that the slippage between electrons and the magnetic flux facilitates reconnection, and can even result in fast reconnection that lacks one of the outflow jets. Through comparing a case where the diamagnetic drift is supported by the temperature gradient with a companion case that has a density gradient instead, we identify a robust suppression mechanism. The drift of the x-line is slowed down locally by the asymmetric nature of the current sheet and the resulting tearing modes, then the x-line is run over and swallowed by the faster-moving following flux.

PACS numbers: 94.30.Cp, 52.35.Vd, 52.35.Py, 96.60.Iv

Introduction—The explosive release of magnetic energy through magnetic reconnection is ubiquitous in laboratory, space, and astrophysical plasmas \cite{1}. The formation of a thin, kinetic-scale, current sheet is the requirement for fast reconnection \cite{2} \cite{3}, but not all thin current sheets seemingly unstable to reconnection undergo reconnection. In a realistic situation, on both sides of the current sheet the pressures are not the same (i.e., asymmetric) and the magnetic fields are not anti-parallel (i.e., the magnetic shear angle \(\phi \neq 180^\circ\)), which induces the diamagnetic drifts of electrons and ions in the outflow direction of reconnection. It is a consensus that a strong drift may hinder magnetic reconnection \cite{4} \cite{14}. However, the fundamentals of how the suppression of reconnection occurs remains unclear, especially in collisionless plasmas.

The diamagnetic suppression of tearing modes (i.e., a linear mode that spontaneously leads to reconnection) \cite{4} \cite{12}, among many other ideas, was extensively explored in order to model the sawtooth crashes that spoil the magnetic confinement in fusion devices \cite{13} \cite{16}. In particular, researchers want to explain why the reconnection associated with these crashes usually does not completely consume the available flux \cite{17} \cite{19} after an abrupt onset \cite{6} \cite{20}, which suggests a suppression of reconnection. The suppression is reflected in the reduction of the growth rate of tearing modes by the diamagnetic drift frequency, \(\omega_j^*\). For instance, a suppression criterion \(\omega_j^* > \gamma_0\) is observed through examining the saturation of magnetic islands in two-fluid models \cite{14} \cite{17}. Here \(\gamma_0\) is the growth rate of tearing modes without the drift effect, and \(j = i, e\) for ions and electrons respectively.

On the other hand, recent work examines the nonlinear development of reconnection \cite{13} \cite{14} by comparing the diamagnetic drift speed, \(U_j^* = cB \times \nabla P_j/(n q_j B^2)\), with the characteristic Alfvén speed, \(V_A\), which is the typical reconnection outflow speed in non-drifting cases \cite{21}. Swisdak et al. \cite{14} performed the first particle-in-cell (PIC) simulations to study this drift effect in collisionless reconnection. They observed that the x-line drifts with electrons at a speed \(\sim U_e^*\). In this letter, velocity symbols in unbolded font are in the reconnection outflow direction (i.e., \(\hat{x}\)) unless otherwise specified. Due to the opposite sign of charges, ions drift against electrons and the x-line motion. This fact led them to hypothesize a suppression mechanism that is satisfied when the drift speed of ions in the x-line frame is larger than the Alfvén speed, i.e., \(|U_i^* - U_e^*| > V_A\). In this scenario, they argued that one of the outflow jets can not develop, hence reconnection is suppressed. Swisdak’s criterion is widely used to interpret the occurrence distribution of reconnection at the magnetosphere of Earth \cite{22} \cite{23} and Saturn \cite{24} \cite{25}, and in the solar wind \cite{26} \cite{27}. However, recent gyro-kinetic simulations \cite{28} were conducted to test this criterion in the low shear angle \(\phi \ll 1\) (i.e., very strong guide field) and low plasma-\(\beta\) (\(\sim 0.1 - 0.01\)) limit, and conclude that this suppression condition is not generally satisfied. In these simulations, the pressure gradient is decomposed into a combination of density and temperature gradients, \(\nabla P_j = T_j \nabla n + n \nabla T_j\). The discrepancy was attributed to the coupling of reconnection with additional instabilities driven unstable by the density \cite{29}, electron temperature \cite{28} \cite{30} or ion temperature \cite{31} gradients.

In this letter, we describe in details the development and suppression of reconnection in the regime with a drift velocity \(|U_i^* - U_e^*| > V_A\), and a moderate magnetic shear angle \(\phi \sim 90^\circ\). This is the stable limit of Ref. \cite{14}, and this limit requires the difference of plasma-\(\beta\) on both sides of the current sheet to be large \cite{32}, i.e., \(\Delta \beta \gg 1\). In the two cases discussed, reconnection under a drift supported by \(\nabla n\) is more or less suppressed, as expected, but reconnection persists under a drift supported by \(\nabla T\). We find that the divergence of the full pressure tensor, \(\nabla \cdot P_e\), in the generalized Ohm’s law allows the slippage between the electrons and magnetic flux at the outflow region. This facilitates reconnection and even results in fast reconnection that lacks one of the outflow jets. Through comparing these two cases, we further demonstrate that the asymmetric nature of the current sheet in the \(\nabla n\)-
case slows down the drift of the x-line, leading the following flux to run over and swallow the x-line. A lower bound for this new suppression mechanism is proposed, and it is different from that suggested in Ref. [14] since the drift of ions are not required.

| TABLE I: Asymmetric feature of Runs |
|-------------------------------------|
| Case | $T_1$ | $T_2$ | $n_1$ | $n_2$ | $B_{1y}$ | $B_{2y}$ | $[U^*_e - U^*_i]$ |
|-----|------|------|------|------|-------|-------|-----------------|
|     |      |      |      |      |       |       | $\nabla T$ |
|     |      |      |      |      |       |       | 12.1 1.21 |
|     |      |      |      |      |       |       | $\nabla n$ |
|     |      |      |      |      |       |       | 1.8 0.18 |

$\nabla T$ setup—Kinetic simulations were performed using the particle-in-cell code - VPIC [33]. The asymmetric configuration employed has the magnetic profile, $B = B_x [0.5 + \alpha_1 \tanh(z/\lambda)]^2 + B_y^2$, density $n = n_0 [1 - \alpha_2 \tanh(z/\lambda)]$, temperature $T = [\alpha_3 - B_z^2/2]/n$ to satisfy the force balance. The pressure gradient is the same for the two cases considered here and the $\nabla T (\nabla n)$-case has an asymmetric temperature (density) profile in the $z$-direction. We initialize $B_y = 0.22 B_{y0}$, $\alpha_1 = 0.55$, $\alpha_3 = 0.55$ and $\alpha_4 = 0.37$. We use $\alpha_2 = 0.82$ for the $\nabla n$-case and $\alpha_2 = 0$ for the $\nabla T$-case. To make a better comparison with the runs in Ref. [14], the 2D simulation plane is then rotated (with respect to the $z$-axis) to the plane where the reconnecting components are equal, $|B_{1x}| = |B_{2x}| = B_0$. Here the subscripts “2” and “1” indicate the side at $z > 0$ and $z < 0$ respectively. The resulting asymmetries are summarized in Table I. The magnetic fields are normalized to the reconnecting field $B_0$ and the guide field strength at the location of $B_x = 0 \sim 2$. Densities are normalized to $n_0$. Spatial scales are normalized to the ion inertial length $d_i \equiv c/\omega_{pi}$, where the ion plasma frequency $\omega_{pi} \equiv (4\pi n_0 e^2/m_i)^{1/2}$. Time scales are normalized to the ion gyro-frequency $\Omega_{ci} \equiv e B_0/m_i c$. For these two cases, the effective Alfvén speeds $V^2_A = (|B_{1x}| + |B_{2x}|)/[4\pi m_i (n_1/|B_{1x}| + n_2/|B_{2x}|)]$ are designed to be the same. This $V_A \equiv d_i/\Omega_{ci}$ hence will be used to normalize velocities. The temperature is normalized by $m_i V^2_A$. The initial thickness of the current sheet is $20 d_i$, and it is different from that suggested in Ref. [14] since the drift of ions are not required.

$\nabla T$ case—Contrary to the heuristic prediction proposed in Ref. [14], reconnection proceeds under such a high $|U^*_e - U^*_i|/V_A$. A reconnection rate $R \sim 0.05$ is sustained, and the x-line drifts in a rather steady velocity $U_{xline} \sim 0.5 V_A$ as shown in Fig. 1(a)-(b). Here $R \equiv (\partial U_e/\partial t)/(B_0 V_A)$ with $U_e \equiv \max(\psi) - \min(\psi)$ along the $B_x = 0$ trajectory and $\psi$ is the in-plane magnetic flux. The $V_{ex}$ at time $15/\Omega_{ci}$ overlaid with the contour of $\psi$ is shown in (c). We can understand the composition of $V_{ex}$ from the momentum equation $m_e \nu \vec{V}_e/dt = -e n_0 \vec{E} + \vec{v}_e \times \vec{B}/c - \nabla \cdot \vec{P}_e$. We consider a subsonic regime where the $\nabla v_e$ term is negligible [35]. By curling the rest of this equation with $\vec{B}$ leads to $-e n_0 \vec{E} \times \vec{B} - \vec{v}_e B^2/c + \vec{B} (\vec{V}_e \cdot \vec{B})/c - \nabla \cdot \vec{P}_e \times \vec{B} = 0$, which shows that the perpendicular flow is the combination of the $\vec{E} \times \vec{B}$ drift and diamagnetic drift: $v_{c,\perp} \sim \eta \vec{E} \times \vec{B}/B^2 - c \vec{B} \times \nabla \cdot \vec{P}_e/(enB^2)$.

We plot the x-component of electron drifts along the $B_x = 0$ trajectory in Fig. 1(d). These velocities along this trajectory are perpendicular to the local magnetic field, hence are relevant to the transport of magnetic structures inside the current sheet. To good approximation, with $B_x = 0$

$$V_{ex} = v_{c,\perp} \approx -\frac{cE_z}{B_y} - \frac{c\partial_y P_{exe}}{n e B_y}. \quad (1)$$

![FIG. 1: Features of the $\nabla T$-case.](image-url)
local drift speed near the x-line drops to a steady value and laxes into a kinetic equilibrium. Note that, although the ions, since the x-line to form a jet. A similar observation applies for the electrons left of the x-line, the electrons are not repelled leftward of the x-line, the electric field (red) at the left side of the x-line, which indicates the slippage between electrons and flux. Hence this term (pink) suggests that the pressure anisotropy contributes significantly to this slippage, while the difference between \( \nabla \cdot \mathbf{P}_e \cdot \hat{y} \) and \( \nabla \cdot \mathbf{P}_e \cdot \hat{y}_n \) closer to the x-line is attributed to the nongyrotropy \[36, 37\].

In addition, we can estimate the advection speed of the in-plane flux. In 2D, we can write \( \mathbf{B} = \hat{y} \times \nabla \psi + B_y \hat{y} \). By performing \( \hat{y} \times \partial_t \mathbf{B} + c \nabla \times \mathbf{E} = 0 \) gives \( E_y = (1/c) \partial_t \psi \). This leads the y-component of the electron force balance, \( \hat{y} \cdot (\mathbf{E} + v_e \times \mathbf{B} = -1/(en) \nabla \cdot \mathbf{P}_e \) at where \( B_z = 0 \) into an advection equation, \( \partial_t \psi + U_\psi \partial_x \psi = 0 \). The estimated advection velocity of \( \psi \) is
\[
U_\psi = V_{ex} - \frac{e \nabla \cdot \mathbf{P}_e \cdot \hat{y}}{enB_z}.
\] (2)

This expression is valid at the region where \( B_z \neq 0 \). This also excludes the singular x-line where \( \psi \) is generated and the \( \nabla \cdot \mathbf{P}_e \) term should be treated as a source term. This \( U_\psi \) in Fig. (d), although noisy, follows well with the measured \( V_{ex} \). In this case \( U_\psi \) and \( V_{ex} \) do not match well with \( V_{ex} \), which again implies a significant slippage that facilitates reconnection.

\[ \nabla \cdot \mathbf{n} \text{ case - } \] On the other hand, the suppression becomes pronounced in the \( \nabla \cdot \mathbf{n} \)-case. For the simulations presented here, the induced x-line does not reconnect. However, over longer times tearing modes are triggered and then suppressed, resulting in a periodic burst of reconnection as shown in Fig. 2(a). This cyclic behavior reveals the nature of suppression.

Fig. 3(b)-(d) show the contours of \( \psi \) and \( V_{ex} \) around the period of the first burst of reconnection at time 16, 20 and 24/\( \Omega_{ci} \). The induced x-line remains inactive in (b). The tearing modes with a significant growth are triggered at the trailing edge of the primary island in (c), which boosts the reconnection rate up to \( \sim 0.05 \). In (d), these tearing islands do not propagate and hence are run over and swallowed by the following flux that maintains a steady positive velocity \( \sim 4V_A \). This motion completely shuts off the reconnection. The tendency is also reflected in the profile of \( V_\psi \) (purple), which follows the trend of \( V_{ex} \). Due to the asymmetric nature of the current sheet, a trough in the \( V_\psi \) profile develops with the x-line (red) sitting at the bottom as shown in Fig. 3(b). The negative slope at the left side of the x-line indicates this tendency of running-over. The birth of tearing modes further diverts the electron flow to the upper side of tearing islands, and this only deepens the \( V_\psi \) trough in (c), which eventually results in the running-over in (d). The same reason explains why tearing modes only become feasible temporarily at the edge where the \( V_\psi \) profile has a positive slope, which delays the running-over. In contrast, for the \( \nabla \cdot \mathbf{T} \)-case shown in Fig. 1(e), the current sheet and the resulting tearing modes are more or less symmetric. Hence the tearing islands and the induced x-line can pick up the peak drift velocity to advect flux. The
FIG. 3: The long term evolution of the $\nabla n$-case. In (a), the normalized reconnection rate, $R$. Panels (b), (c) and (d) show the $V_{ex}$ map overlaid with the in-plane flux at times marked in (a). The $V_{ex}$, $V_{ix}$ and $V_\psi$ along the trajectory where $B_z = 0$ (the yellow curves in the 2D map) are plotted underneath each panel. The ion gyro-radius, $\rho_i$, is also shown in (c). The oblique yellow dashed line tracks the motion of the following flux, while the three nearly vertical yellow dashed lines track the motion of tearing modes and active x-lines therein.

in-plane magnetic structures in the $\nabla T$-case all propagate in a positive velocity $\sim V_A$ as indicated by the $V_\psi$ in Fig. 3(d). These x-lines will not be run over by the following flux and reconnection persists. As opposed to the asymmetric feature of tearing modes, a potential magnetization of the ions does not cause the local reduction of $V_\psi$ in the $\nabla n$-case, since the local ion gyro-radius ($\sim d_i$) does not decrease at the tearing islands and the ion drift $V_{ix}$ is barely affected as shown in Fig. 3(c). These observations suggest that this suppression mechanism does not require the drift of ions, and hence differs from that proposed in Ref. [11]. It is also interesting to point out that the burst of fast reconnection can last longer if tearing modes grow faster and form a spatially longer tearing-mode-chain, so that the following flux needs more time to swallow them one-by-one. This phenomenon is seen in a companion case with hotter electrons (e.g., a case with $T_i/T_e = 0.3$, not shown).

FIG. 4: The velocity profiles around the x-line in the x-line drift frame. Here the x-line is at $x = 0$ and the slippage is assumed negligible. In (a), $\Delta U_x > V_A$. In (b), $\Delta U_x < V_A$.

**Model**-- To model the lower bound for this suppression, we consider an ideal situation without slippage, i.e., $V_\psi \approx V_{ex} \approx U_x^* + U_{E \times B}$. The asymmetric nature of the current sheets causes a trough in the profile of $U_x^*$ locally near the x-line, while the magnetic tension force in $d_i$-scale tends to drive electrons to the Alfvén speed $V_A$ outwardly from the x-line [38], and this effect enters the $U_{E \times B}$ drift. Fig. 4(a) shows a case where the depth of the trough, $\Delta U_x^*$, is larger than the asymptotic value of $|U_{E \times B}| \sim V_A$. Note that, these velocities are measured in the x-line drift frame. The resulting $V_\psi$ has a trough with a negative slope at the left side of the x-line, hence the x-line will be run over. If $\Delta U_x^* < V_A$ as in (b), the $V_\psi$ profile only has a positive slope and is free from this suppression mechanism. The $\nabla n$-case falls into the category of Fig. 4(a). The $\nabla T$-case falls into the category of (b) after accounting for the slippage. Based on these observations, we conclude that the suppression of reconnection, at least, requires $\Delta U_x^* > V_A$.

**Summary and Discussion**-- A new suppression mechanism caused by the local reduction of flux transport speed is identified inside the ion diffusion region. This robust mechanism can completely shut off reconnection after a rapid onset. The magnitude of $\Delta U_x^*$ is determined by the asymmetric nature of the current sheet and the resulting tearing modes. For the $\nabla n$-case, the asymmetric nature may come from the mismatch between the x-line and the flow stagnation point (i.e., $\delta_{x2}/\delta_{x1} = B_2/B_1$ and $\delta_{x2}/\delta_{x1} = n_2B_1/n_1B_2$ in Ref. [39]), which does not develop with only the asymmetry in temperature, as the $\nabla T$-case. In the limit of strong density asymmetry, the tearing modes and active x-lines therein barely drift as in the $\nabla n$-case presented here, then the $\Delta U_x^*$ is similar to the equilibrium $U_x^*$ of the current sheet. The lower bound for this suppression reduces to a simpler form $U_x^* > V_A$.

This study also shows that reconnection with only one jet in the x-line drift frame is possible due to the slippage between plasmas and the magnetic flux. This fact suggests the need for improving the identification of reconnection events at Earth’s magnetopause, and this could be studied using NASA’s on-going Magnetospheric Multiscale mission that is capable of evaluating $\nabla \cdot \mathbf{P}_e$ rou-
