Probing the metallic energy spectrum beyond the Thouless energy scale using the singular value decomposition

Richard Berkovits
Department of Physics, Jack and Pearl Resnick Institute, Bar-Ilan University, Ramat-Gan 52900, Israel

Disordered quantum systems feature an energy scale know as the Thouless energy. For energy ranges below this scale, the properties of the energy spectrum can be described by random matrix theory. Above this scale a different behavior sets in. For a metallic system it has been long ago shown by Altshuler and Shklovskii that the number variance should increase as a power law with a power dependent only on the dimensionality of the system. Although tantalizing hints for this behavior have been seen in previous numerical studies, it is quite difficult to verify this prediction using the standard local unfolding methods. Here we use a different unfolding method, i.e., the singular value decomposition, and establish a connection between the power law behavior of the scree plot (the singular values ranked by their amplitude) and the power law behavior of the number variance. Thus we are able to numerically verify the Altshuler and Shklovskii’s prediction for disordered 3D, 4D, and 5D single-electron Anderson models on square lattices in the metallic regime. The same method could be applied to systems such as the Sachdev-Ye-Kitaev model and various interacting many body models for which the many body localization occurs. It has been recently reported that such systems exhibit a Thouless energy and analyzing the spectrum’s behavior on larger scales is of much current interest.

I. INTRODUCTION

Weakly disordered quantum systems are known to exhibit a universal behavior of their energy spectrum which depends only on the symmetry of the system\textsuperscript{4}. The statistical properties of the energy spectrum do no depend on the details of the system, and are described by a random matrix model with the same symmetry. This behavior is extremely useful in identifying and understanding various properties of metallic systems\textsuperscript{2–6}. As pointed out by Altshuler and Shklovskii\textsuperscript{7}, this universal behavior holds only for energy scales which are below the Thouless energy $E_T$. The Thouless energy corresponds to $E_T = \hbar/t_T$ where the Thouless time $t_T = L^2/D$ ($L$ is the linear dimension of the sample, $D$ the diffusion constant) depicts the time it takes for a diffusing particle to sample all the system. For shorter times the motion is not yet diffusive and therefore dependent on details of the local system. Thus, above this energy scale, the behavior of statistical properties of the spectrum will diverge from the random matrix predictions. The canonical measure used to probe this deviation is the number variance\textsuperscript{1}, defined as the variance in the number of energy levels within an energy window for an unfolded energy spectrum. Defining a window of size $E$, one can count the number of levels within this window for a given realization of disorder and obtain the average number of levels, $\langle n(E) \rangle$, and the variance, $\langle \delta^2 n(E) \rangle = \langle (n(E) - \langle n(E) \rangle)^2 \rangle$, where $\langle \ldots \rangle$ denotes an average over an ensemble of different realizations of disorder. For the Wigner-Dyson random matrix ensemble (Gaussian orthogonal ensemble, GOE): $\langle \delta^2 n(E) \rangle = 0.44 + (2/\pi^2) \ln(\langle n(E) \rangle)$, while for the localized regime $\langle \delta^2 n(E) \rangle = \langle n(E) \rangle$. Metallic systems correspond to the Wigner-Dyson random matrix predictions up to a energy window of size $E_T$ and Altshuler and Shklovskii\textsuperscript{7} predict that for $E > E_T$ the number variance will follow $\langle \delta^2 n(E) \rangle \propto \langle n(E) \rangle^{d/2}$, where $d$ is the dimensionality.

The deviation of the number variance from the random matrix logarithmic behavior to a stronger than linear behavior at large energies has been observed in metallic systems\textsuperscript{8,9}. Recently, it has gained much interest beyond the traditional single-particle disordered systems. Stronger than linear deviations of the number variance beyond a certain energy scale have been seen in the context of Sachdev-Ye-Kitaev (SYK) model\textsuperscript{10,11}, many body localization systems\textsuperscript{12–14,18} and the generalized Rosenzwieg-Porter random matrix model\textsuperscript{15,16}. In all these cases it was argued that the energy for which the number variance becomes stronger than linear corresponds to the inverse of the time scale for which the motion can no more sample the whole phase space.

Although the prediction for the behavior of the number variance on scales larger than the Thouless energy is straightforward, it is not easy to corroborate even for simple single-particle systems such as the Anderson model with any degree of certainty. We shall see that the main problem is the local unfolding procedure, as has been noted by previous studies\textsuperscript{17,18}. Here we intend to address this challenge of verifying Altshuler and Shklovskii prediction\textsuperscript{7}. We shall illustrate in detail that a straightforward study of the number variance using local unfolding is fraught with ambiguities. Therefore, it is clear that a different tack is needed. Here we will suggest that a couple of new measures, which are based on singular value decomposition (SVD) method. This method has been used to classify whether a system follows Wigner or Poisson statistics\textsuperscript{19–21}, and recently to identifying non-ergodic extended signature in the Rosenzwieg-Porter model\textsuperscript{22}. As we shall demonstrate, using the SVD method to replace the short range unfolding provides a clearer way to study the behavior of the energy spectrum beyond the Thouless energy.

The paper is organized as follows. In the next section...
(Sec. II) we define the single particle Anderson model on a square lattice for different dimensionalities. The following section (Sec. III) presents the numerical results for the number variance using local unfolding and discusses the challenges it presents. Section IV shows the use of the SVD to tease out the behavior of the large energy scales. In its first subsection (IV A) we give an overview of the SVD method. In the next subsection (IV B) we use the SVD to perform a global unfolding by filtering out the low modes of the singular values which corresponds to the global features of the energy spectrum and thus retaining only the fluctuations. Establishing analytically a connection between the Power spectrum of these fluctuations and the number variance enables us to glean the long range behavior of the energy spectrum. Since there is a connection between the power spectrum and the scree plot of the singular value modes (the singular values ranked by their amplitude), as established in subsection IV B, the scree plot may be used to read off the long range spectrum properties. This is used in subsection IV C in order to verify the dependence of the number variance at a critical disorder, i.e., in order to study the long range spectra behavior deep in the critical regime of the Anderson transition at a critical disorder.

In the Ye-Kitaev model and disordered interacting many body systems, we can apply the SVD to additional interesting systems such as Sachdev-Ye-Kitaev model and disordered interacting many body systems. In section V we discuss the possibility of applying the SVD to different dimensionalities. The following section (Sec. II) we define the single particle Anderson model on a square lattice for different dimensionalities. In order to study the long range spectra behavior deep in the critical regime, we consider many body localization models known to exhibit many body localization.

II. MODEL

We consider a simple one-particle Anderson model on a $d$ dimensional square lattice with sites at $\vec{r} = j_x \hat{x} + j_y \hat{y} + \ldots$, where $j_i = 1, 2, \ldots L_i$, and $L_i$ is the length in the $i$ direction. Each site has an on-site energy $\epsilon_{\vec{r}}$ chosen randomly from a box distribution in the range $-W/2 \ldots W/2$. Nearest neighbor hopping between the sites is considered, with a hopping matrix element set to one. The Hamiltonian is written as:

$$H = \sum_{\vec{r}} \epsilon_{\vec{r}} c_{\vec{r}}^{\dagger} c_{\vec{r}} + \sum_{\vec{r}} \sum_{\vec{a}} c_{\vec{r}+\vec{a}}^{\dagger} c_{\vec{r}},$$

where $c_{\vec{r}}^{\dagger}$ is the creation operator at site $\vec{r}$ and $\vec{a} = \pm \hat{x}, \pm \hat{y}, \ldots$ are unit vectors to the nearest neighbor sites.

This model is known to exhibit a metal-insulator transition at a critical disorder $W_C = 16.5$ for the 3D case, $W_C = 34.5$ for the 4D case, and $W_C = 57.5$ for the 5D case. In order to study the long range spectra behavior in the metallic regime, we concentrate on values of disorder much lower than the critical disorder, i.e., $W = 5$ and $W = 10$. Using exact diagonalization we calculate the eigenvalues for the $L^d \times L^d$ matrices, where we consider hyper-cubes of size $L = L_x = L_y, \ldots$ and hard wall boundary conditions. For the 3D case we consider sizes $L = 20, 24, 28$, corresponding to $L^3 = 8000, 13824, 21952$, while in the 4D case we evaluate sizes $L = 9, 10, 11, 12, 13$, resulting in $L^4 = 6561, 10000, 14641, 20736, 29561$, and for the 5D case $L = 6, 7, 8$, which amounts to $L^5 = 7776, 16807, 32768$. Unless noted differently, in all cases the spectra was calculated for 3000 different realizations.

III. NUMBER VARIANCE

To begin, we shall investigate the behavior of number variance at large energies as function of the dimensionality and system size. Using the $L^d$ eigenvalues, $\epsilon_i$, obtained for each realization, the spectrum is locally unfolded. The following local unfolding was applied: Each eigenvalue obtains the value $\epsilon_i = \epsilon_{i-1} + 2p(\epsilon_i - \epsilon_{i-1})/(\epsilon_{i+p} - \epsilon_{i-p})$ where $\langle \ldots \rangle$ is an average over realizations, and we have checked that the results are not very sensitive to the value of $p$ (for all results presented here $p = 6$ was chosen). The number variance is also averaged over 41 positions of the center of the energy window, $E(k)$, equally spaced around the band center, where the furthest point is no more than $1/15$ of the bandwidth from the center. For each $E(k)$, the number of states in a window of width $E$ centered at $E(k)$, $n_k(E)$ is evaluated, then the averages $\langle n(E) \rangle$ and $\langle n^2(E) \rangle$ are taken over all positions of the center $k$ and all realizations.

One expects that for $E < E_T$, the number variance will follow the Wigner Dyson prediction, while for $E > E_T$, $\langle n^2(E) \rangle \sim \langle n(E) \rangle^{d/2}$. This is probed in Fig. 1 where the variance $\delta^2 n(E)$ as function of $\langle n(E) \rangle$ for 3D, 4D, and 5D samples of different sizes are plotted. In all cases the GOE logarithmic behavior is followed for small energy windows. For energy windows larger than the Thouless energy, $\langle n \rangle > \langle n(E_T) \rangle$, a stronger than linear growth sets in. The Thouless energy depends on disorder and dimensionality, and we chose the strength of disorder for each case ($W = 5$ for 3D and 4D samples, $W = 10$ for 5D samples) so $E_T$ will be such that $\langle n(E_T) \rangle$, which corresponds to the dimensionless conductance $g$, will be of order $O(10^{-100})$. Above $\langle n(E_T) \rangle$ the variance crosses over to a different behavior and shows a stronger than linear increase. Fitting the variance to $\langle n(E_T) \rangle^{\beta}$ behavior shows that beyond the crossover region, there is a wide range for which the power law $\beta$ is constant, and at even higher energies deviations appear.

This general behavior is seen for all dimensionalities and system sizes. For the 3D case with $W = 5$, the Thouless energy, i.e., where the variance starts to diverges from the Wigner Dyson (GOE) predictions, appears around $\langle n(E_T) \rangle \sim 20$. Fitting $\beta$ after the variance has substantially diverged from the logarithmic behavior, i.e., in the region $50 < \langle n(E) \rangle < 150$ results in $\beta = 1.23, 1.26, 1.31$ for $L = 20, 24, 28$, which seems to hold well up to $\langle n(E) \rangle < 350, 400, 450$ correspondingly. Above these values, the numerical computed variance tapers off to a more moderate increase. This may be finite size effects or a problem with local unfolding on larger energy scales. For 3D we expect $\beta = 1.5$, while the values we see are below, but increasing with the system size $L$. Thus, it may be that for much larger system sizes the
predicted value would be reached, nevertheless, extrapolating from the change in $\beta$ as $L$ increases one concludes that much larger systems will be needed in order to reach $\beta = 1.5$.

A similar behavior is seen for higher dimensionality. For the 4D case with the same disorder $W = 5$ the Thouless energy is larger and $\langle n(E_T) \rangle \sim 80$. This is expected since as the number of nearest neighbors to which the particle can hop increases the effect of disorder should decrease. Again, we fit $\beta$ for the region for which the variance begins to significantly diverge from GOE, $400 < \langle n(E) \rangle < 800$, $\langle n(E) \rangle \sim (\langle n(E) \rangle)^{\beta}$, and obtain $\beta = 1.52, 1.56, 1.65, 1.68, 1.73$ for $L = 9, 10, 11, 12, 13$. Once more, values which are below the expected power law $\beta = 2$, but becoming closer as the system size is increase.

The same pattern emerges also for 5D samples where the disorder was increased to $W = 10$ in order that the Thouless energy will be similar to the value obtained for lower dimensions $\langle n(E_T) \rangle \sim 60$. A fit for the region $400 < \langle n(E) \rangle < 800$ yields $\beta = 1.75, 1.83$ for $L = 7, 8$, far from the expected $\beta = 2.5$. Once more, for 4D and 5D samples, for large energy scales, $\langle n(E) \rangle > 1500$, the increase in the variance tappers.

Thus, although with much effort probing even larger sizes may be possible, it nevertheless does not seem very promising, and we shall turn in a different direction. This direction is based on the singular value decomposition method and would be described in the following section.

**IV. SINGULAR VALUE DECOMPOSITION**

**A. General**

Singular value decomposition (SVD) is a mathematical method applied mainly in the field of data analysis and has enjoyed growing popularity. In this method a matrix $X$ of size $M \times P$ (not necessarily Hermitian nor square) is decomposed to a multiplication of three matrices. In general the relevant data is arranged by rows and columns, where the specifics depend on the application. Thus, $X$ is decomposed to $X = USV^T$, here $U$ and $V$ are $M \times M$ and $P \times P$ matrices, while $S$ is a $M \times P$ diagonal matrix of rank $r = \min(M, P)$. $\sigma$ stands for the $r$ diagonal elements of $S$ are called the singular values (SV) of $X$. The SV are always positive and could be arranged in decreasing order so $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_r$. The Hilbert-Schmidt norm of the matrix $||X||_{HS} = \sqrt{\text{Tr}(X^TX)} = \sqrt{\sum_k \lambda_k}$ (where $\lambda_k = \sigma_k^2$). Thus, $X$ can be written as a sum of matrices $X^{(k)}$, where $X_{ij}^{(k)} = \sum_k \sigma_k X_{ij}^{(k)}$, and $X^{(k)} = U_{ik}V_{kj}^T$. Since the SV are ordered by amplitude, the main contribution to $X$ comes from the first $m$ modes, and $X$ may be approximated by, $\tilde{X} = \sum_{k=1}^{m} \sigma_k X^{(k)}$, for which $||X||_{HS} - ||\tilde{X}||_{HS}$ is minimal. Thus, if $\lambda_k$ become relatively small for some value $m$ $\tilde{X}$ could be used as an approximation of $X$. Moreover, by plotting $\lambda_k$ as function of its ranking $k$ (known as a scree plot in the con-

![FIG. 1. The variance $\langle \delta^2 n(E) \rangle$ as function of $\langle n(E) \rangle$ for 3D (a); 4D (b); and 5D (c) samples of different sizes. (a) 3D samples of sizes $L = 20, 24, 28$ and disorder $W = 5$. For $\langle n \rangle < \langle n(E_T) \rangle \sim 20$, Wigner Dyson (GOE) behavior is followed as can be seen clearly in the inset. In the region $50 < \langle n(E) \rangle < 150$ a fit to $\langle n(E) \rangle \sim (\langle n(E) \rangle)^{\beta}$ is performed, resulting in $\beta = 1.23, 1.26, 1.31$ for $L = 20, 24, 28$ correspondingly. Above $\langle n(E) \rangle > 80$, deviations from the power law become apparent and the variance increases more moderately. In the inset the deviation from the GOE logarithmic behavior at $\langle n(E_T) \rangle \sim 20$ can be clearly seen. (b) 4D samples of sizes $L = 9, 10, 11, 12, 13$ and disorder $W = 5$. For $\langle n \rangle < \langle n(E_T) \rangle \sim 80$ Wigner Dyson (GOE) behavior is followed. In the region $400 < \langle n(E) \rangle < 800$ a fit to $\langle n(E) \rangle \sim (\langle n(E) \rangle)^{\beta}$ is performed, resulting in $\beta = 1.52, 1.56, 1.65, 1.68, 1.73$ for $L = 9, 10, 11, 12, 13$ correspondingly. In the inset the behavior for larger values of the energy window is depicted. Clearly, the variance does not continue to grow at the same pace. (c) 5D samples of sizes $L = 7, 8$ and disorder $W = 10$. For $\langle n \rangle < \langle n(E_T) \rangle \sim 60$, Wigner Dyson (GOE) behavior is followed as can be seen clearly in the inset. In the region $200 < \langle n(E) \rangle < 400$ for $L = 6$ and the region $400 < \langle n(E) \rangle < 800$ for $L = 7, 8$ a fit to $\langle n(E) \rangle \sim (\langle n(E) \rangle)^{\beta}$ is performed, resulting in $\beta = 1.75, 1.83$ for $L = 7, 8$ correspondingly. Again, as shown in the inset, for larger values of $\langle n(E) \rangle$ a weaker growth in variance appears.](image-url)
text of statistical factor analysis\textsuperscript{27}) one may gain some insight into the statistical properties of the data in $X$.

Here we study an ensemble of $M$ realizations of disorder each with $P$ eigenvalues. For the SVD analysis we construct a matrix $X$ of size $M \times P$ where $X_{nm}$ is the $p$ level of the $m$-th realization. After carrying out SVD on $X$, the singular values squared $\lambda_k$ are ranked from the largest to the smallest. This approach has been applied to the spectrum of disordered systems in several studies\textsuperscript{19–22}. As is usual in the SVD analysis in these studies the first few $\lambda_k (k \leq O(1))$ correspond to global features of the spectra. Larger SV ($\lambda_k$) show a power law behavior $k^{-\alpha}$ with $\alpha = 2$ at the Poisson regime and $\alpha = 1$ for the Wigner regime.

Here we will examine whether the large scale behavior of the energy can be gleaned with the help of SVD. We will use two different approaches which will eventually lead to similar results. In the first, we shall use SVD to perform a global unfolding. The second will use the scree plot to tease out a power law behavior for the relevant energy scale.

### B. Global Unfolding

The idea behind global unfolding using SVD is to filter out the low modes which represent the global behavior, while retaining the lower modes that encode local fluctuations. We shall illustrate the global unfolding procedure for an ensemble of realization for the 3D case of size $L = 28$. As previously described, we construct a matrix $X$, where each row contains $P = 4096$ eigenvalues around the center of the band for each realization and $M = 4096$ columns representing the different realizations. Matrices $U$, $V$ and $\Sigma$ are numerically extracted and the $r = M$ diagonal terms $\sigma_k$ are ranked according to amplitude, from the largest to the smallest. The matrices $X^{(k)}$ are constructed out of $U$ and $V$, paying attention to the correct sign\textsuperscript{28}. As can be seen in Fig. 2 where the SVD values of $\lambda_k = \sigma_k^2$ are plotted, the first couple of modes $\lambda_{k=1,2}$ are clearly orders of magnitude larger than the rest. Lower modes seem to follow a power law $\lambda_k \sim k^{-\alpha}$. For $3 < k < 20$, $\alpha = 2.5$ fits well while for $k > 50$, $\alpha = 1$. Intuitively, one would guess that modes $3 < k < 20$ correspond to longer energy scales for which $E > E_T$ while $k < 50$ to shorter energy scales. Nevertheless, one would like to confirm this assertion.

There has been much work devoted to studying the expression of the statistics of local fluctuations on the power spectrum of these fluctuations. It has been shown that the power spectrum of the local fluctuation of chaotic systems is different than the power spectrum of integrable systems\textsuperscript{17,29–32}. Specifically, the power spectrum of the local fluctuations for each realization is defined as:

$$F_k^i = \left| \frac{1}{P} \sum_{j=1}^{P} \delta_j^i \exp \left( \frac{-2\pi i kj}{r} \right) \right|^2,$$

and averaging over all realizations $F_k = \langle F_k^i \rangle$. For chaotic systems $F_k \sim k^{-1}$, while for integrable (localized) systems $F_k \sim k^{-2}$. The power spectrum of the local fluctuations for the 3D case of size $L = 28$ is presented in Fig. 3. As for the singular value modes, two regimes are apparent. The high frequencies follow a power law $F_k \sim k^{-\gamma}$, with $\gamma = 1.1$, while after a crossover a range of low frequencies fit to $\gamma = 2.5$. Thus the high fre-
frequencies ($k > 50$, corresponding to small energies), the behavior of the power spectrum is close to what was observed in other chaotic (GOE) systems\textsuperscript{17,29–32}. There are a couple of interesting observations that one can draw from the behavior of the low frequencies. The first has to do with the equivalence between the power laws of the SVD scree plot for low modes and for the for the power law at low frequencies, i.e., $\alpha = \gamma = 2.5$, and for the high modes and frequencies $\alpha \sim \gamma \sim 1$. Such correspondence between the power law of the SVD modes and power spectrum frequencies has been noted for the energy spectrum in Refs. 19–22, and elucidated in Ref. 33. The correspondence also determines the energy scale of the singular values. The $k$-th Fourier transform frequency corresponds to an energy scale $P\Delta/2k$, thus the region for which GOE statistics holds is of order of $40\Delta$, not to far from the estimation of the Thouless energy obtained via the number variance. As can be seen in Fig. 2, also the singular value modes follow the GOE expectation ($\alpha = 1$) up to $k = 50$. Moreover, both curves show a similar behavior and one may assume that the scree plot depicts the same physics as the power spectrum of the globally unfolded energy spectrum and that the energy scales probed by the modes of the SVD are similar to the energy scales of the Fourier transform.

In order to substantiate the proposed connection between the energy scale and the SVD mode number, we split the the contribution the modes into two parts: $\delta_j^{(I)} = \sum_{k=3}^{30} \sigma_k X_{i,j}^{(k)}$ and $\delta_j^{(II)} = \sum_{k=31}^{\infty} \sigma_k X_{i,j}^{(k)}$. As can be seen in Fig. 4a for the same realization presented in the inset of Fig. 2, $\delta_j^{(II)}$ indeed depicts longer range fluctuations, while $\delta_j^{(II)}$ portrays short scale fluctuations. This could be confirmed by the power spectrum of the fluctuations $\delta_j^{(I,II)}$. For the low singular value modes the corresponding power spectrum (see Fig. 4b) frequencies are in the range of $4 < k < 20$ with the same power law $\alpha = \gamma = 2.5$, while for the higher modes the corresponding frequencies are at $k > 100$ with a slope $\gamma = 0.9$. Thus one can reasonable conclude that low modes in the SVD probe the large energy scales of the spectrum.

Another observation is that both for the power spectrum and for the SVD scree plot the lower frequencies/modes exhibit a power law with a slope of $1 + d/2$. The slope of the power spectrum could be generally associated to the value of the power of the variance\textsuperscript{34,35}. As detailed in the appendix, indeed, the expected value of the power spectrum $\gamma = 1 + d/2$ can be analytically explained. In the next sub-section we will further substantiate these observation.

C. Scree Plot

As we have previously seen the scree plot of the singular values characterize the behavior of the large energy scale by showing a power law behavior of the low modes corresponding to $1 + d/2$ power, clearly distinct from $\alpha = 1$ seen for higher modes. Here we would like to check whether this behavior is robust for different system sizes, disorder strength, ranges of the spectrum and dimentionality.

First we continue to present results for the SVD modes scree plot for 3D samples in Fig. 5. All results are for an
ensemble of $M = 3000$ different realizations at each size and disorder strength. Three different sizes $L = 20, 24, 28$ are considered, each for two different strength of disorder $W = 5$ (as we saw corresponds to $n(E_T) = g = 20$) and $W = 10$ ($n(E_T) = g = 5$, makes sense since $E_T \sim 1/W^2$). Thus, for the $W = 5$ samples we are deep in the metallic regime where the Altshuler and Shklovskii’s predictions are expected to hold, while for $W = 10$ we are already closer to the localized regime ($g = 1$). Indeed, one can see that the range of modes for which the GOE behavior holds ($\alpha \sim 1$) is much larger for the weaker disorder. The weak disorder singular values fall on top of each other for the lower modes, with a slope of $\alpha = 2.5 = 1 + d/2$. Then for higher modes the slope switches to the GOE behavior ($\alpha \sim 1$) where the value of $k$ for which the switch occurs is higher as the system size increases. We speculate that this is the result of the fact that for larger systems there are more eigenvalues in the range of $L^3/2$. We shall further substantiate this assertion shortly. A similar behavior is seen for the stronger disorder ($W = 10$) although the slope deviates a bit from $\alpha = 1 + d/2$ and is closer to $\alpha = 2.3$. This is not surprising since the prediction in Ref. 7 were obtained using diagrammatic reasoning, strictly valid only deep in the metallic regime ($g \gg 1$).

In Fig. 6 we examine the influence of the change in the range of the eigenvalues, $P$ on $\lambda_k$. Indeed, the main influence of narrowing the range of $P$ is to shift the crossover from the $\alpha = 2.5$ slope to the GOE $\alpha = 1$ slope to lower values of $k$. This makes sense, since the smaller the range, the smaller is the number of energies larger than the Thouless energy in this range. Thus, when one wants to focus on energies beyond the Thouless energies, and there is a limit on the ensemble size $M$, one should expand $P$ to the largest available range, even if $P \gg M$.

The number of the realizations taken in the ensemble, $M$, also plays a role in the behavior of the SVD modes. As can be seen in Fig. 7 the slope for the low mode does not depend on the number of realizations in the ensemble $M$ and remains $\alpha = 2.5$ for all values of $M$. On the other hand, for the high modes the slope varies from $\alpha = 0.85$ at $M = 1000$ to $\alpha = 1$ for the largest number of realizations $M = 8000$, in line with the predictions for the Wigner-Dyson statistics. Such behavior has been previously seen in the study of the generalized Rosenzweig-Porter where the scree plot of the SVD modes for large $k$ (the GOE regime) also follow a slope of $\alpha \sim 0.82$ for small values of $M$. This behavior was attributed there to the fact that there $M \ll P$. This fits well with our current results where as $M$ grows $\alpha$ is closer to one.

Finally, we wish to examine the dependence on dimensionality of the SVD modes. As we have seen for $d = 3$ and argued analytically, we expect to observe a slope of $\alpha = 1 + d/2$ for the lower modes crossing over to a slope of $\alpha = 1$ at higher modes. Indeed, the scree plot shown in Fig 8 confirms that the slope of the low modes corresponds to $\alpha = 3$, and $\alpha = 3.5$ for $d = 4$ and $d = 5$, as expected from the number variance behavior at large energies predicted in Ref. 7. Higher modes show a slope of $\alpha = 0.95$ for both $d = 4$ and $d = 5$, close to the expected value of $\alpha = 1$, except for the largest length at each dimensionality for which the number of realizations $M = 1000$ is smaller than for the other length, and the slope is $\alpha = 0.83$. This is in line with the behavior shown in Fig. 7.
The behavior of the low mode slopes is not sensitive to the ensemble size and a slope of $\alpha = 2.5$ is seen for all values of $M$. Lower modes are more susceptible to the number of realizations. For small values of $M = 1000$ the slope fits $\alpha = 0.85$ for $M = 1000$ at higher modes, while it shifts to $\alpha = 1$ at $M = 8000$.

V. DISCUSSION

The detection of the Thouless energy in the spectrum of weakly disordered chaotic systems has long been achieved by detecting the deviation from the expected Wigner-Dyson logarithmic dependence of the number variance. Thus, it could be assumed that the number variance will also reveal the behavior of the spectrum at energy scales beyond the Thouless energy derived by Altshuler and Shklovskii. Indeed, a stronger than linear dependence has been frequently observed, nevertheless, extracting the expected power law behavior from the number variance after local unfolding has turned out to be far from trivial. As has been shown here, the number variance does indeed show a $\langle n^2(E) \rangle \sim \langle n(E) \rangle^\beta$ behavior for a significant range of levels. Although the value of $\beta$ rises as the size of sample increases towards the expected $d/2$ value, it remains hard to extrapolate a value with the largest samples we are able to compute.

By taking the route of the SVD, it is possible to overcome these difficulties. The SVD essentially decomposes the spectrum to modes, where the low modes (large amplitudes) capture the longer range features. As we have shown, the SV modes are in a sense similar to the Fourier transform frequencies, and show similar regularities of the frequencies and modes. Nevertheless, the SVD saves the need to first unfold and then perform a power analysis over all realizations and finally average, thus it is a much more concise method. Moreover, since the contribution of the lowest modes ($e_j$) filtered out is custom set for each realization $i$, one overcomes the problem of individual realization global variations raised in Ref. 18.
the number variance $\langle \delta^2 n(E) \rangle \propto \langle n(E) \rangle^{d/2}$ is $\gamma = 1 + d/2$.

Following McDowell et. al.\textsuperscript{34} the local fluctuations $\delta_j = \delta_j^i/\Delta$ may be rewritten as:

$$\delta_j = \frac{1}{k_{\text{max}} - k_{\text{min}}} \sum_{k=k_{\text{min}}}^{k_{\text{max}}} \sqrt{2K_k^2} \cos(K_j + \phi_k),$$

(A.1)

where $k_{\text{min}}, k_{\text{max}}$ is the range for which the power spectrum exhibits a particular power law behavior with slope $\gamma$, $K = 2\pi k/r$, and $\phi_k$ is a phase. The number variance $\delta_j^2 n_j(l\Delta)$ for a particular realization $i$ where the energy window $E$ starts at the energy of the averaged $j$th eigenvalue $j\Delta$ and ends at $(j+l)\Delta$ ($E = l\Delta$) could be written as:

$$\delta_j^2 n_j(l\Delta) = (\delta_{i+l}^j - \delta_{i}^j)^2.$$  

(A.2)

Substituting $\delta_j^i$ by Eq. (A.1) and averaging over the beginning of the energy window $j$ and the phase $\phi_k$ one obtains:

$$\langle \delta_j^2 n_j(l\Delta) \rangle = \frac{1}{r-1} \sum_{j=1}^{r-1} \frac{(k_{\text{max}} - k_{\text{min}})^2}{(2\pi)^2} \sum_{k=k_{\text{min}}}^{k_{\text{max}}} 2K_k^2 \cos(K(j+l) + \phi_k - \cos(Kj + \phi_k))$$

$$\langle \cos(K(j+l) + \phi_k) - \cos(Kj + \phi_k) \rangle^2.$$  

(A.3)

Performing the integration over $\phi_k$ and summation over $j$ retaining only the $l$ dependent part one obtains:

$$\langle \delta_j^2 n_j(l\Delta) \rangle \sim \frac{1}{k_{\text{max}} - k_{\text{min}}} \sum_{k=k_{\text{min}}}^{k_{\text{max}}} F_k \cos(Kl).$$  

(A.5)

Replacing the summation with an integration and using the power law dependence of the power spectrum leads to:

$$\langle \delta_j^2 n_j(l\Delta) \rangle \sim \int_{K_{\text{min}}}^{K_{\text{max}}} dK K^{-\gamma} \cos(Kl) \sim l^{\gamma-1}. \quad (A.6)$$

Thus since followin Altshuler and Shklovskii\textsuperscript{7} $\langle \delta_j^2 n_j(l\Delta) \rangle \sim l^{d/2}$, one concludes that the power spectrum should exhibit a slope $\gamma = d/2 + 1$.
