Abstract

Background:

Epstein-Barr virus (EBV) is the cause of infectious mononucleosis (IM), a self-limited lymphoproliferative disorder among patients. EBV usually infects B-lymphocytes rather than T-lymphocytes. The clinicopathologic features of the idiopathic thrombocytopenic purpura (ITP) patients complicated with EBV-positive IM have been rarely described.

Case presentation:

We describe a case of a 19-year-old man complained with epistaxis and thrombocytopenia for one year, who was admitted to hospital for high grade fever after catching a cold. A lot of petechiae were found on the skin of both lower limbs and both hands during physical examination. Multiple enlarged lymph nodes could be touched in both sides of the neck. Ultrasound examination showed abnormal lymph nodes enlargement on both sides of the neck and supraclavicular area, and a strong echo mass was found in the liver. Serological tests for EBV revealed high level of IgM and IgG antibodies against viral capsid antigen (VCA), virus DNA quantitative<1000 UI/mL. CD8-positive cytotoxic T cells accounted for up to 92.94% by flow cytometry. T cells were positive for CD38, CD57 and HLA-DR marker. Bone marrow cytology showed that the proportion of lymphocytes had increased considerably, and the rate of abnormal lymphocyte was as high as 29.5%. EBV virus encoded RNA was demonstrated in lymph node biopsy by in-situ hybridization (ISH) analysis. Immunohistochemically, there were more CD8-positive cells than CD4-positive cells in lymph node biopsy. The expression of CD7 was missing. CD99 was diffuse positive. The MIB-1/ki-67 labeling index was about 70%. EBER in situ hybridization revealed positive signals located in the nucleus. The patient was diagnosed as Infectious mononucleosis complicated with idiopathic thrombocytopenic purpura. The patient was hospitalized and discharged after recovery.

Conclusions:

ITP patients complicated with EBV-positive IM have been rarely reported in the literature. Comprehensive understanding of its clinicopathological features will help diagnose of this disease.

Background

Infectious mononucleosis is a self-limited disease caused by Epstein-Barr virus infection. Primary infection usually occurs among children and adolescents. The most common symptoms of acute EBV infection are fever, lymphadenopathy, tonsillitis and fatigue [1]. Epstein-Barr virus is generally considered to only infect B cells [2,3], that is, to activate lymphocytoblast cells and immunoblast cells. However, some scholars have found that EBV can also infect T cells, and immunotoxins tests revealed that EBV could infect CD4-positive helper/inducer T cells [4]. Here we present an unusual case of ITP patient complicated with IM which was caused by EBV infection of T cells. Previously reported cases were reviewed.
Case Presentation

A 19-year-old man suffered from ITP for one year. He had high fever after catching cold with the highest temperature reaching 39℃ three days ago, accompanied by right nosebleed. The patient had no pharynx, night sweats, chest tightness, asthma, cough, phlegm, abdominal pain, diarrhea, black stool, hematuria or other discomfort. There were many petechiae on the skin of both lower limbs and both hands (figure 1, 2). Multiple enlarged lymph nodes could be touched in both sides of the neck. From ultrasound examination, enlarged lymph nodes with abnormal structure were identified on both sides of the neck and supraclavicular area. Lymph nodes were checked in the axilla and groin of both sides without obvious abnormal structure. A strong echo mass measuring 0.6×0.4cm could be found in the liver. Laboratory tests showed that red blood cells, 4.8×10^{12}/L (4.3-5.8×10^{12}/L); white blood cells,11.4×10^9/L(4.0-10×10^9/L); platelets,13×10^9/L(125-300×10^9/L). Serological tests showed high level of EBV, which revealed IgM and IgG antibodies against VCA. Virus DNA quantitative <1000UI/mL. Flow cytometry analysis revealed a 92.94% population of CD8-positive cytotoxic T cells in peripheral blood, CD4/CD8=0.07, and T cells were positive for CD38, CD57 and HLA-DR marker. Bone marrow cytology showed that the proportion of lymphocytes had remarkably increased, and the rate of abnormal lymphocyte was as high as 29.5%. In-situ hybridization (ISH) analysis showed EBV virus-encoded RNA was positive in Lymph node biopsy.

Histologically, hematoxylin and eosin stain revealed partial thickening of lymph node capsule. Hemorrhage and lymphocyte infiltration were observed in the tissue outside the capsule. The subcapsular sinus was dilated with infiltration of lymphocytes and plasma cells. Some arteriole wall thickened and lumen dilated in cortical area. A few follicular germinal centers were enlarged, irregular in shape, and the polarity disappeared (figure3). Some follicles were crowded and the interfollicular area disappeared. Paracortical area expanded with mixed lymphocytes of different sizes. Activated lymphocytoblast cells, immunoblast cells and plasma cells were observed, while few mitosis and a lot of endothelial veins were observed.

In the immunohistochemistry study, there were more CD8-positive cells than CD4-positive cells in lymph node biopsy. CD21 highlighted the irregular follicular dendritic meshwork. The expression of CD7 was negative. CD99 was diffusely positive. The MIB-1/ki-67 labeling index was approximately 70%. EBER-ISH demonstrated that EBER positive signals located in the nucleus, and the maximum number of positive cells was approximately 60/HPF. By using double staining in-situ hybridization with immunostaining against CD20, the CD20-positive cells were EBER negative cells, as well as CD3-positive cells were EBER positive cells. Based on the finding above, the patient was diagnosed as ITP complicated with EBV-positive IM. The patient was hospitalized and received treatment.

Discussion

Infectious mononucleosis is a self-limited disease [5], it can occur in both men and women, mainly in children and young adults. The symptoms are fever, pharyngeal pain, fatigue and lymphadenectasis. A
few patients have swelling in tonsils, spleen and liver [6, 7]. "Abnormal lymphocytes" can be found in peripheral blood, they are usually identified as CD8-positive T cells [8]. Epstein-Barr virus serum antibody increases in peripheral blood. The prognosis is usually favorable. Histologically, the capsule of lymph nodes are thin [9]. In this case, the capsule thickened in the focal area, and there was lymphocyte infiltration outside the capsule. We speculate that the patient may had experienced ITP symptoms such as hemorrhage in the lymph node capsule, which might be a reaction of the IM patient to bleeding.

EBV infects B cells with C3d complement receptor (CD21), and EBV infection induces CD8-positive cytotoxic T cells against B cells. These activated T cells can be detected in patients' peripheral blood. The immunophenotype of our case showed that the lymphocytes were mainly CD8-positive T cells in the Paracortical enlargement, which expressing CD30, EBER and CD3. Studies have shown that mature T cells express low levels of CD21, but EBV infected T cells are rare [10]. This case showed that EBV infected CD3 and CD8 positive T cells. Maybe there are some unknown receptors in the CD3 and CD8 positive T cells which led to the direct EBV infection in the ITP patients. This conclusion needs more cases.

Both IM and systemic EBV + T-cell lymphoma of childhood are diseases that present with scattered, atypical, EBV-positive cells and, because of these similarities, these entities may be mistaken for one another. The latter distinguishes from IM by the presence of poor clinical prognosis, usually within a few days to a few weeks, rapid disease progression and even death can occur. Then we can also exclude T/NK cell chronic active EBV infection (caebv-t /NK), whose diagnostic criteria is fever lasting for at least 3 months.

Conclusions

In summary, we described a rare case of ITP combined with IM. The case showed that EBV infected CD3 and CD8 positive T cells. The patient was treated with drugs (omeprazole enteric capsule and prednisone) after discharged. During the followed two years he was normal. Further question needs to be studied: the relationship between CD8 and CD99 positive T cells in IM patients. The case of ITP combined with IM has rarely been reported. Infectious mononucleosis should be taken into consideration when ITP patient has fever and there is lymph node enlargement, and pathological biopsy should be performed. There is still a lack of large-scale data on how to make effective diagnosis and proper treatment. This report makes a preliminary exploration.

List Of Abbreviations

EBV: Epstein-Barr virus; IM: infectious mononucleosis; ITP: idiopathic thrombocytopenic purpura; VCA: viral capsid antigen; HLA-DR: Human Leukocyte Antigen-DR; ISH: in-situ hybridization; EBER: Epstein-Barr virus-encoded small RNA; HPF: high power field.

Declarations
Ethics approval and consent to participate
This case study was approved by the Institutional Ethics Committee of Central theater of war general hospital, Wuhan, China.

Consent for publication
Written informed consent was obtained from the patient for the publication of this case report and any accompanying images.

Availability of data and materials
All data analyzed during this case are included within the article.

Competing interests
The authors declare that they have no competing interests.

Funding
Not applicable.

Authors’ contributions
WQ collected the clinical data and drafted the manuscript. ZJS, WQ, LQ and RY made the pathological diagnosis. LQ and RY made revision to the final manuscript and provided the funding support. All authors read and approved the final manuscript.

Acknowledgments
Not applicable.

A few follicular germinal centers were enlarged, irregular in shape (×100). B. Most of them had small to medium-sized nuclei, and there were also some immunoblast-like cells with cytologic atypia (×400). C. Most of the EBER-positive cells (brown) were actually atypical T lymphocytes without expression of CD20 (red) (×400). D. EBER-positive T cells (brown) were immunostained positive for CD8 (red) (×400).
