(Dated: 24 December 2018)

We study the flow of membranal fluid through a ring of immobile particles mimicking, for example, a fence around a membrane corral. We obtain a simple closed-form expression for the permeability coefficient of the ring as a function of the particles’ line fraction. The analytical results agree with those of numerical calculations and are found to be robust against changes in particle number and corral shape. From the permeability results we infer the collective diffusion coefficient of lipids through the ring and discuss possible implications for collective lipid transport in a crowded membrane.

I. INTRODUCTION

Numerous studies continue to unravel the complex structure and dynamics of biological membranes [1–3]. The basic component of biomembranes, the fluid lipid bilayer, contains a variety of embedded objects such as mobile and immobile proteins and domains of different lipid composition. The resulting highly crowded environment affects the dynamics of all its constituents.

Indeed, it has been known for over three decades that the cortical cytoskeleton hinders the diffusion of membrane proteins and lipids [4–7]. Later studies connected this inhibition with the subdivision of the membrane into domains (“corrals”), enclosed by immobile proteins (“fences and pickets”) [3, 8–12]. In such a compartmentalized membrane, a mobile protein or lipid diffuses within one of the domains until it escapes and moves into the next domain, and so on. Many experimental and theoretical studies have been devoted to the resulting anomalous dynamics [13–29].

The most common techniques used in the experimental studies are fluorescence recovery after photobleaching (FRAP) [4–6, 12], single-particle tracking (SPT) [10, 12–15, 17, 19], and fluorescence correlation spectroscopy (FCS) [30–32]. Note that these measurements follow either single molecules (SPT and FCS) or dilute dispersions of fluorescent probes (FRAP), and hence do not yield the collective dynamics of the membranal fluid. If we want to write the diffusion equation for the dense bulk fluid of lipids, the relevant diffusion coefficient is the collective one, which can differ by orders of magnitude from the single-lipid coefficient [33, 34]. It is of interest, therefore, to account for collective lipid transport, which is expected to be strongly affected by membrane compartmentalization.

In the present work we attempt to account for the collective transport of lipids into or out of a membrane corral. We address the physics of the transport hindrance due to the corral boundary, going beyond the schematic descriptions offered by previous works, such as a potential barrier or a stochastic gate [18, 20–29]. The collective diffusion coefficient across the fence can be inferred from the fence’s permeability coefficient, since the two are directly related via the fluctuation-dissipation theorem.

In order to calculate the permeability coefficient we start, as in most theories of membrane flow, from the classical work of Saffman and Delbrück (SD) [35, 36]. In this simplified model the membrane is perceived as a flat slab of homogeneous viscous fluid embedded in a much less viscous solvent, and the proteins — as cylindrical inclusions spanning the thickness of the membrane. Over the years the SD model has been applied to diverse problems [37], among which are the diffusion of single proteins [35, 38], the hydrodynamic coupling of two or several proteins [39–42], the influence of inclusions on the effective viscosity of the membrane [41, 43, 44], and the effect of the inclusion’s shape on its diffusion [45–47]. In particular, the presence of a solid substrate [48–51] or immobile obstacles [44, 52] was shown to have a strong effect on membrane dynamics.

A more realistic theoretical description of membrane dynamics would require an understanding of lipid transport through membrane obstructions. This would be also essential for predicting and interpreting experimental results. As a step in this direction, we adapt the SD model to treat membranal flow through a ring-like fence of immobile inclusions.

In the next section we describe our model in detail. In section III we present the results of numerical calculations, analytical derivation of the permeability coefficient, and the resulting collective diffusion of lipids. Finally, in section IV we discuss the results and their implications, and indicate the limitations of our model.

* Due to the relatively low viscosity of the solvent, the possible protrusion of the inclusion out of the membrane usually has an insignificant effect on the dynamics.
II. MODEL

We consider an assembly of N membrane proteins arranged equidistantly in a ring-like structure of arbitrary shape and perimeter L (see Fig. 1). The proteins are represented as cylindrical inclusions of radius a, embedded in a membrane of thickness h and viscosity $\eta_m$, within a surrounding aqueous solution of viscosity $\eta \ll \eta_m$. We define an effective 2D viscosity, $\mu = \eta_m h$, the ring density (line fraction) $\phi = 2Na/L$, and the cutoff length (the SD length) $\kappa^{-1} = \mu/(2\eta)$. We assume that the corral size is much smaller than the SD length, $L \ll \kappa^{-1}$.

In the system under consideration, the ring is immobile. A pressure difference $\Delta p$ gives rise to a lipid flow $u$, which is perturbed in the vicinity of each immobile inclusion. Since the proteins interact hydrodynamically, this perturbation around each individual protein $i$ is affected by all other proteins $j \neq i$. In order to keep each protein $i$ in place, a restoring force $F_i$ is applied, for example, by the cytoskeleton. In the continuum limit, the permeability $P$ of the corral to lipid flow is defined as the ratio between the normal flow and the pressure difference, $P = \langle u \cdot n \rangle/\Delta p$ (Darcy’s law), where $n$ is a unit normal to the corral boundary at a given point, and the average is taken over the perimeter. For a discrete chain of particles we define the normal to the polygonal ring at a given particle, $n^i$, as the unit vector along the mean direction of the normals to the adjacent two chords.

For the sake of analytical convenience, we reconstruct the problem in the following way. Instead of immobile particles within an imposed flow, we may consider the near-equivalent problem of mobile particles driven by normal forces $F^i = F n^i$ in an ambient membrane (Fig. 1). This reciprocal equivalence is exact in the limit of an infinite, straight-line arrangement, due to translational invariance (momentum conservation). As we shall see, our results for the permeability (both analytical and numerical) are insensitive to the curvature of the ring, which proves the validity of this approximation. In the inverted description, the flow caused by the motion of each driven particle influences the motions of all other particles in the assembly. The permeability then can be rewritten as the ratio between the average normal velocity of the particles and the total normal force per unit length,

$$P = \frac{L}{NF^i \cdot n^i} = \frac{2a}{\phi F} \langle v^i \cdot n^i \rangle. \quad (1)$$

In order to find the average over the $N$ particles, the normal velocity of each particle is to be calculated as a function of the positions of all particles.

Our primary goal is to calculate the permeability $P$ as a function of line fraction $\phi$ and particle number $N$. Note that we work within the continuum limit for the membrane, under the rough assumption that the size of the lipids is negligible relative to the gaps between the corral proteins.

III. RESULTS

A. Numerical calculation

The velocity of particle $i$, given the positions of all other particles in the ring, is given by

$$v^i = F \left( B_s n^i + \sum_{j \neq i} G^{ij}_{\alpha\beta} n^j_{\beta} \right), \quad (2)$$

$$B_s = \frac{1}{4\pi\mu} \left( \ln \frac{2}{\kappa a} - \gamma \right). \quad (3)$$

Equation (2) contains two terms. The first is the velocity of particle $i$ due to the force acting on it, where $B_s$ is the self-mobility as calculated by SD, and $\gamma \approx 0.58$ is Euler’s constant. The second term represents the hydrodynamic interactions between particles $i$ and $j \neq i$, positioned at $r^i$ and $r^j$, where $G^{ij}_{\alpha\beta} \equiv G_{\alpha\beta}(r^j - r^i)$ is the coupling mobility tensor and $\alpha, \beta = x, y$ are membrane coordinates.

We consider two possible approximations for the interaction tensor $G$. The simple approximation assumes the particles to be point-like objects (the Stokeslet limit) $G^i \equiv \delta^i$.

$$G_{\alpha\beta}(r) = \frac{1}{4\pi\mu} \left[ \left( \ln \frac{2}{\kappa r} - \gamma - \frac{1}{2} \right) \delta_{\alpha\beta} + \frac{r_\alpha r_\beta}{r^2} \right], \quad a \ll L \ll \kappa^{-1}. \quad (4)$$

† If a membrane is surrounded by two different fluids with different viscosities $\eta_1$ and $\eta_2$, then $\kappa^{-1} = \mu/(\eta_1 + \eta_2)$. 
As we have shown in a recent publication [54], this tensor fails above a relatively large density, \( \phi > \phi_c \simeq 0.5 \), producing inward motion under outward force. When this tensor is used for a circular ring of equidistant particles, we get negative permeabilities above that density, as shown in the inset of Fig. 2 (light triangles) and as calculated below. In Ref. [54] we derived an improved interaction tensor, overcoming the problem of negative response,

\[
G^{+}_{\alpha\beta}(r) = \frac{1}{4\pi\mu} \left[ \left( \ln \frac{2}{\kappa r} - \gamma - \frac{1}{2} + \frac{a^2}{r^2} \right) \delta_{\alpha\beta} + \left( 1 - \frac{2a^2}{r^2} \right) \frac{r_{\alpha}r_{\beta}}{r^2} \right], \quad a \ll L \ll \kappa^{-1},
\]

where \( r = |r^{i} - r^{j}| \). When this corrected tensor is substituted in Eqs. (1) and (2), we find strictly positive permeability coefficients (Fig. 2, dark circles) for the same circular ring of particles. These results are physical, but not exact. For instance, for a sealed corral, at \( \phi = 1 \), we get a small positive permeability, while in reality the permeability should vanish.

In order to check the sensitivity of the results to the shape of the corral, we study two additional ring shapes, using the function

\[
\tilde{R}(\theta) = R \left[ 1 + \rho \sin(q\theta) \right],
\]

and examining two modulations, \( q = 2, 3 \), in addition to the basic circular case, \( q = 0 \). See the shapes in Fig. 4. The same number of particles should correspond to the same line fraction in order to achieve a meaningful comparison between the three shapes. Therefore, for each shape, we calculate the value of \( R \) such that the perimeter \( L \) remains unchanged. As shown in Fig. 4, the permeabilities of the three rings are indistinguishable. This is the conclusion when using either \( G \) or \( G^{+} \).

### B. Analytical calculation

We calculate analytically the expression for the permeability in the Stokeslet limit and compare it to the numerical results. This calculation is strictly valid in the continuum limit, \( N \to \infty \) and \( a \to 0 \) such that \( Na = L\phi/2 \) is finite, but we shall see that practically it works for remarkably small particle numbers. We number the particles along the ring by the index \( m \in [0, N-1] \) and take particle \( m = 0 \) to be identical to \( m = N \) to close the ring. Thus, particle...
FIG. 2. Permeability coefficient as a function of line fraction for a circular corral of \( N = 100 \) particles. The coefficient is normalized according to \( \overline{P} = \left( \frac{\mu}{a} \right) P \). The line fraction \( \phi \) is varied while keeping the particle number constant by changing the protein size according to \( a = \phi L/(2N) \). Triangles show results of numerical summation using the interaction tensor \( G \) [Eq. (4)] (Stokeslet limit), and circles — using the corrected, positive-definite tensor (PDT), \( G^+ \) [Eq. (5)]. In the numerics we normalize the parameters such that \( L = 2\pi \) and \( \kappa = 10^{-3} \). The solid line presents the analytical result, which is independent of \( L \) and \( \kappa \) [Eq. (12)]. The inset focuses on the failure of the tensor \( G \) for \( \phi \gtrsim 0.5 \).

FIG. 3. Numbering the particles in the ring.

\( m = N - 1 \) can be marked also as \( m = -1 \), etc. See Fig. 3. According to Eq. (2) and focusing on particle \( m = 0 \), we need to calculate the following sum:

\[
S_\alpha \equiv \sum_{m=1}^{N-1} G^{m,0}_{\alpha\beta} n^m_{\beta},
\]

where \( G^{m,0}_{\alpha\beta} \equiv G_{\alpha\beta}(r^m - r^0) \). This sum accounts for the hydrodynamic interactions of a given particle \( (m = 0) \) with the rest of the particles in the ring \( (m \neq 0) \).

In the first step we transform the discrete sum into a continuous integral using the Euler-Maclaurin formula:

\[
S_\alpha \simeq \int_1^{N-1} dm \, G^{m,0}_{\alpha\beta} n^m_{\beta} + \mathcal{R}^{(1)} + \mathcal{R}^{(2)},
\]

where \( \mathcal{R}^{(1)} = \frac{1}{2} \left[ G_{\alpha\beta}^{1,0} n_1^{\beta} + G_{\alpha\beta}^{-1,0} n_{-1}^{\beta} \right] \), and \( \mathcal{R}^{(2)} = -\frac{1}{12} \left[ \partial_m G_{\alpha\beta}^{1,0} |_{m=1} - \partial_m G_{\alpha\beta}^{-1,0} |_{m=-1} \right] \).

Including the two leading corrections \( \mathcal{R}^{(1)} \) and \( \mathcal{R}^{(2)} \) is sufficient to fit the numerical results.

In the second step we exploit the fact that \( G \) is divergenceless, \( \partial_\alpha G_{\alpha\beta} = 0 \), due to the assumed incompressibility of the lipid flow. Since we apply normal forces along the entire closed boundary of the domain, according to the
divergence theorem, the full integral along the ring vanishes, \( \int_0^N dm G_{\alpha\beta}^{m,0} n_\beta^m = 0. \) Hence,
\[
\int_1^{N-1} dm G_{\alpha\beta}^{m,0} n_\beta^m = - \int_1^1 dm G_{\alpha\beta}^{m,0} n_\beta^m.
\]
(9)

In this way we have reduced the summation of many long-range interactions between a given particle and the rest of the ring to an integration over a much smaller domain around the particle, containing only its two nearest neighbors. In the third step we obtain the structural functions \( r(m) \) and \( n(m) \). For \( N \gg 1 \) we can assume a small curvature, in which case the neighbors of the given particle are positioned at a distance \( \ell_0 \simeq L/N \), and
\[
r_{m,0} = |r_1 - r_0| \simeq |m|\ell_0, \quad n_{m} \simeq n_0.
\]
(10)

Note that now \( m \) is restricted to the interval \([-1, 1]\).

In the fourth and last step we substitute Eq. (10) into Eq. (9). The resulting normal component of the sum can be written as
\[
S_n \equiv S_n n_\alpha = - \int_1^1 dm g(|m|\ell_0) + g(\ell_0) - \frac{\ell_0}{6} g'(\ell_0),
\]
(11)
where \( g(r) \) is the isotropic part of the interaction tensor \( G \),
\[
g(r) = \frac{1}{4\pi\mu} \left( \ln \frac{2}{\kappa r} - \gamma - \frac{1}{2} \right).
\]

Let us consider for a moment a circular ring such that the velocities of all particles are equal by symmetry. Performing the integration in Eq. (11) while using Eqs. (1), (2) and (7), we obtain our central result for the permeability of the corral,
\[
P(\phi) = \frac{a}{2\pi\mu \phi} \left( \ln \frac{2}{\phi} - \frac{4}{3} \right).
\]
(12)

Note that the dependence on the cutoff length \( \kappa^{-1} \) has disappeared.

Despite the aforementioned assumptions, this result is robust against changes in particle number and ring shape. The solid line in Fig. 2 shows excellent agreement with the Stokeslet numerical results for \( N = 100 \). Fits of similar quality are obtained for smaller particle numbers, as demonstrated in Fig. 5.

Concerning the non-circular rings, studied in the preceding section, the analytical calculation clarifies why the numerical results presented in Fig. 4 are insensitive to the ring shape. The divergence theorem is valid for any closed domain, so that the interactions to the small immediate vicinity of an arbitrarily chosen particle, thus making the rest of the ring immaterial.

Recall that results obtained within the Stokeslet approximation become unphysical above a certain density \( \phi_c \) [54]. This unphysical behavior is overcome by the corrected interaction tensor \( G^+ \) of Eq. (5). Unfortunately, the procedure leading to Eq. (12) cannot be applied to \( G^+ \), since the extra \( 1/r^2 \) term causes divergence of the integral in Eq. (11). The inset of Fig. 2 compares the numerical and analytical results and shows that for \( \phi \gtrsim 0.4 \) numerical summation with the \( G^+ \) tensor should be used. In addition, Eq. (12) allows us to calculate \( \phi_c \) analytically. We find that \( P(\phi) > 0 \) for \( \phi < \phi_c = 2e^{-4/3} \simeq 0.527 \).

In the opposite limit, \( \phi \to 0 \), Eq. (12) gives indefinitely large permeability. In reality, there is a finite \( \phi \) below which Darcy’s law no longer holds, and our theory becomes irrelevant.

C. Consequences for collective lipid diffusion

One of the important biological implications of the permeability is for the collective (gradient) diffusion of lipids across a fence of membrane inclusions, under the continuum assumption that the distance between the obstacles is much larger than the lipid size. While the permeability coefficient is the ratio between flow velocity and pressure difference across the fence, the gradient diffusion coefficient \( D \) is the ratio between flux and concentration gradient. The two are related via
\[
D(\phi) = 2aKP(\phi),
\]
(13)
where \( K = c(\partial p/\partial c)_T \) is the isothermal compression modulus of the membrane, \( c \) is the lipid concentration, and \( 2a \) is the assumed thickness of the fence. Thus, Eqs. (12) and (13) give a simple prediction for the collective diffusion coefficient across a ring-like or an infinitely long, linear fence as a function of the fence’s density.
FIG. 4. Normalized permeability coefficient $\bar{P} = (\mu/a)P$ as a function of line fraction $\phi$ for particle number $N = 30$ and three different ring shapes, obtained by numerical summation in the Stokeslet limit. The three shapes correspond to three modulation modes, according to Eq. (6) with $\rho = 0.3$. The shapes are constructed such that their perimeters are the same, $L = 2\pi$.

Substituting realistic values, $a = 3$ nm, $K = 200$ erg/cm$^2$ [55], $\phi = 0.3$, and $\mu = 10^{-6}$ erg·s/cm$^2$ (surface poise) [37], we get $D \sim 10^3 \mu$m$^2$/s. This value is two orders of magnitude larger than known self-diffusion coefficients of a single lipid [11], as expected for the collective diffusion coefficient in a dense fluid [33, 34]. The high density of the lipid fluid enters through the relatively large value of $K$. According to liquid theory, $D \sim D_s/S(k \to 0)$, where $D_s$ is the self-diffusion coefficient of a single lipid, and $S(k)$ is the structure factor as a function of wavevector $k$. In the

FIG. 5. Normalized permeability coefficient $\bar{P} = (\mu/a)P$ as a function of line fraction $\phi$ for small particle number ($N = 5$). Triangles show the numerical result in the Stokeslet limit and the squares with solid line show the analytical result. Note that the relative errors remain small even for $N = 5$. The inset presents the dependence of the numerical results on particle number for $\phi = 0.3$ and shows the fast convergence of $\bar{P}$ to its continuum value as the particle number increases.
limit of $k \to 0$, $S \sim 1/K$ \cite{33, 56}, and, therefore, $D \sim K$, in line with Eq. \cite{13}.

As mentioned in the previous section, at sufficiently low line fraction the expression \cite{12} becomes invalid. In this limit $D$ should saturate to its value in a neat membrane.

**IV. DISCUSSION**

In this work we have derived the permeability coefficient of a ring of immobile particles, embedded in a fluid membrane. Earlier studies highlighted the distinctive hydrodynamic behavior of the membrane as a quasi-two-dimensional fluid \cite{37, 52}, expressed, for example, in the appearance of logarithmic functions \cite{36}. In the present work this anomaly is reflected by the logarithmic dependence on density in Eq. \cite{12}.

Our results have a broad range of validity with respect to the density of the ring, its shape, and the number of constituent particles. This, in particular, justifies our initial assumption concerning the equivalence between immobile and forced particles regardless of curvature. The resulting permeability is a purely local, intensive property, which is not self-evident in the present case in view of the very long-range (logarithmic) hydrodynamic interactions. In addition, the insensitivity to shape implies that the results also apply for long lines of immobile inclusions away from their edges.

The expression for the permeability allows to calculate the collective diffusion coefficient of lipids into and out of a corral, according to Eq. \cite{13}. In a membrane crowded with such corrals, diffusion through their boundaries, consisting of immobile inclusions, should become the rate-limiting process for lipid transport. Since the permeability undergoes strong suppression with increasing line fraction of proteins in the corral fences (see Fig. 2), we expect a similar suppression of the collective diffusion coefficient of lipids over length scales larger than the corral size, compared to a neat membrane. Note that this suppression does not require a high area fraction of immobile inclusions, but just a high line fraction at the boundaries of the corrals.

The simplified model presented here has several limitations when applied to biomembranes: (a) the ring is never isolated in reality, but rather surrounded by other mobile and immobile intramembranal objects; (b) the membrane is not a continuous fluid, since the lipids have a finite size which is not necessarily negligible compared to the corral proteins; (c) the corral proteins need not be of the same lateral size or arranged equidistantly; and (d) the inclusions are never perfectly immobile. Nonetheless, we believe that our theory should capture the essential characteristics of lipid transport through a ring-like assembly of obstacles.
