Abstract

Cooperativity plays an important role in the action of proteins bound to DNA. A simple, mechanical mechanism for cooperativity, in the form of a tension-mediated interaction between proteins bound to DNA at two different locations, is proposed. These proteins are not in direct physical contact. DNA segments intercalating bound proteins are modeled as a Worm-Like Chain, which is free to deform in two dimensions. The tension-controlled protein-protein interaction is the consequence of two effects produced by the protein binding. The first is the introduction of a bend in the host DNA and the second is the modification of the bending modulus of the DNA in the immediate vicinity of the bound protein. The interaction between two bound proteins may be either attractive or repulsive, depending on their relative orientation on the DNA. Applied tension controls both the strength and the range of protein-protein interactions in this model. Properties of the cooperative interaction are discussed, along with experimental implications.

Keywords: protein, cooperativity, DNA, interactions

The cooperative binding of proteins to DNA plays a significant role in the regulation of gene expression [Owen-Hughes and Workman, 1994] since it allows a sensitive response to small changes in protein concentration. In particular, it is well known that transcription factor proteins [Lodish et al, 1993]
exhibit a significant level of cooperativity [Sun et al, 1997]. The structural basis of the cooperativity is not fully understood [Sun et al, 1997], but it is known that long-range cooperativity is possible through loops [Schlief, 1992], formed as the result of association between two DNA-binding proteins. Looping is also believed to play an important role in gene access control. Cooperativity at shorter distances may be related to specific protein-protein interactions or to a generic cooperativity resulting from structural distortions induced by the binding of a protein to DNA [Lilley, 1995, Nelson, 1995]. For example, the binding of transcription regulation proteins such as the important TATA-box promoters (TPB) involves amino-acid intercalation into the stack of base pairs [Kim, et al, 1993, Werner, et al, 1996]. The result is that kinks are produced—sharp local bending angles in the DNA strand. This deformation may permit a better fit for other DNA-associating proteins, such as the polymerases. Disruptions of the base-pair stacking sequence have no effect beyond about half a turn of the double helix [Kim, et al, 1993, Werner, et al, 1996], so it is expected that this form of cooperativity is restricted to the immediate neighborhood of the primary binding protein. Protein-induced deformations of the DNA strand are not restricted to transcription factors. DNA may wrap itself once or more around a protein as happens in the case of complexation of DNA with nucleosomes, the gyrase enzyme, or bacterial RNA. Interestingly, nucleosome-binding appears to be cooperative with transcription factors [Owen-Hughes and Workman, 1994]. DNA-deforming proteins will be referred to below as “architectural” proteins.

The aim of this article to demonstrate the possibility of a variable-range form of cooperative DNA binding of architectural proteins with a range and strength that is regulated by the tension along the DNA strand. The cooperative interaction between proteins that are not in physical contact, is mediated by the deformation of the intervening DNA strand. In the absence of tension, the proposed mechanism is absent. Our demonstration of the possibility of tension-controlled cooperativity is based on an analysis of the “Worm-Like Chain” (WLC) model of DNA elasticity [Hagerman, 1981, Kam, et al, 1981], which has been used in studies of single protein binding to DNA [Marko and Siggia, 1997]. The WLC model is characterized by a single parameter, a length-scale \( \xi_p \), known as the persistence length. It is the distance over which a (tensionless) WLC maintains orientational order in the presence of thermal fluctuations. That is to say, the autocor-
relation between orientational order at two different locations of the chain falls off with distance, $\ell$, as $e^{-\ell/\xi_p}$. Fitting the results of micro-mechanical in-vitro studies of protein-free DNA chains to the predictions of the WLC model yields good results for a persistence length of about 50 nanometers [Bustamante, et al, 1994, Bensimon, et al, 1994], although longer persistence lengths have been reported by different methods [Bednar, et al, 1995].

We employ the WLC model only to evaluate binding cooperativity due to deformations produced by architectural proteins in sections of the DNA strand that are not in the immediate neighborhood of the binding proteins themselves. The WLC model will not apply reliably when the two proteins are so close together that details of base-pair action (i.e. roll, slide and twist) play an important role in the mediation of their interaction. The primary binding of the protein itself is characterized by two phenomenological parameters: the single protein, zero-tension specific binding free energy $E^{(1)}(s)$ and the DNA bending angle $\alpha$; see Figure 1. The specific binding energy $E^{(1)}(s)$ is a sequence-sensitive quantity that depends on the location of the protein along the chain. It is usually in the range of 10 to 30 $k_BT$ with $k_B$ Boltzmann’s constant and $T$ the temperature in degrees Kelvin. At room temperature $k_BT \simeq 0.6$ kcal/mole. By comparison, the individual ionic bonds between base pairs in DNA are in the range 2-3 kcal/mole, and typical covalent bounds are the order of 60-120 kcal/mole. The index $s$ refers to the position of the protein along the DNA strand. The protein-DNA complex will be assumed to be rigid for the tension levels envisioned, so the bending angle $\alpha$ is independent of tension. The values of $E^{(1)}(s)$ and $\alpha$ must be obtained either experimentally or by detailed structural modelling of DNA-protein interactions.

We will focus on the results of analytical and numerical studies that utilize the WLC model to compute the deformation energy of a DNA chain under tension with two identical architectural proteins attached and separated by a distance $l$. The two proteins are assumed to induce a bend into the DNA strand without any twisting. We find that there is, in general, both an enthalpic and an entropic contribution to the binding cooperativity proposed here [Wang and Giaever, 1988]. The enthalpic cooperative correction to the binding energy $E^{(2)}$ between the two proteins (denoted by 1 and 2) that are separated by a distance $l = |s_1 - s_2|$ assumed large compared to the
characteristic dimensions of the protein is given by

\[
E^{(2)}_{\text{enth}} \simeq E^{(1)}_1(s_1) + E^{(1)}_2(s_2) - 2\alpha^2 k_B T \left( \frac{\xi_p}{\xi(F)} \right) \left( 1 \mp e^{-|s_1-s_2|/\xi(F)} \right)
\]  

(1)

This formula, derived in Appendix A, holds when the bending angle \( \alpha \) is small compared to \( \pi/2 \). The case of large bending angle is discussed later. The plus sign in Eq. 1 refers to the “symmetric” case with the two proteins bound on the same side of DNA while the minus sign refers to the “anti-symmetric” case with the two proteins bound on opposite sides of the DNA (see Figure 1). The chain-tension \( F \) in Eq. 1 is variable but assumed to be in the range of \( 10^{-2} \) to 10 pN. The tension-dependent length-scale \( \xi(F) \) in Eq. 1 is of key importance; it sets the range of the binding cooperativity. This quantity is defined by:

\[
\xi(F) = \sqrt{\frac{\xi_p k_B T}{F}}
\]  

(2)

For a one pN tension, \( \xi(F) \) is about 7 nm, while for a \( 10^{-2} \) pN force it is about 70 nm. However, Eq. 1 is only valid as long as the “tension-length” \( \xi(F) \) is less than the persistence length \( \xi_p \). For larger tensions \( \xi(F) \) is small compared to the persistence length \( \xi_p \approx 50 \) nm. Note that all parameters in Eq. (1) can, in principle, be determined experimentally.

According to Eq. 1, there is no bending-induced cooperativity between two proteins separated by a distance large compared to the tension length \( \xi(F) \). In that limit, the only effect of tension is to reduce the single protein binding energy by an amount per protein \( \Delta E_{\text{enth}} = \alpha^2 k_B T \xi_p F \) (using Eq. 2 to eliminate \( \xi(F) \) in Eq. 1). This tension-induced reduction of the protein binding energy is discussed \[Marko and Siggia, 1997\] for the case of single-protein binding to DNA. For a one pN tension, the binding energy reduction is significant: about 7\( \alpha^2 k_B T \). With increasing tension, the protein will be released from the DNA chain when \( \Delta E_{\text{enth}} \) starts to approach the protein binding free energy \( E^{(1)} \).

\footnote{If the DNA-protein interaction involves a number of turns of the DNA around the protein, then we must add the quantity \( \Delta L F \) to \( \Delta E_{\text{enth}} \), with \( \Delta L \) the excess DNA length wound around the protein. For low tensions \( F \), this correction is small compared to \( \Delta E_{\text{enth}} \), but for a one pN tension, it is comparable.}
A summary of expected values for the cooperative interaction between two bound proteins is displayed in the table 1. It is assumed that the bending angle that each enforces is 45°. Other quantities are appropriate to DNA at room temperature.

When the spacing between the two proteins is reduced to within a distance of order the tension-length $\xi(F)$, then the binding energy increases exponentially for the antisymmetric arrangement while it decreases exponentially for the symmetric arrangement. We can interpret the last term in Eq. 1 as an effective potential energy of interaction, $V_{\text{enth}}(l)$, between two proteins given by:

$$V_{\text{enth}}(l) \cong \mp 2\alpha^2 k_B T \left( \frac{\xi_p}{\xi(F)} \right) e^{-l/\xi(F)}$$

with $l = |s_1 - s_2|$ the interprotein spacing. The minus sign in Eq. 3 is for the anti-symmetric case. In Appendix A we compute $V_{\text{enth}}(l)$ for values of the bending angle $\alpha$ that range up to $\pi/2$. The result is shown in Fig. 2. Note that both the vertical and horizontal axes are dimensionless. The energy has been expressed in units of $2k_B T \left( \xi_p/\xi(F) \right)$, the energy scale of the tension-induced binding energy reduction $\Delta E_{\text{enth}}$ (see Eqs. 1 and 3), while the distance is expressed in units of the tension length, $\xi(F)$. It follows from Fig. 2 that an increase in tension reduces the range of the interaction, as expected from Eq. 2, while it increases the strength of the cooperativity. If the spacing $l$ between the proteins is small compared to the tension length $\xi(F)$, then the effective potential $V(0)$ cancels the $\Delta E_{\text{enth}}$ term in Eq. 1. The enthalpic energy gain obtained by bringing two proteins together along the chain from a large separation is equal to twice $\Delta E_{\text{enth}}$.

For the symmetric case, the effective potential energy is repulsive. The corresponding energy plots are shown in Figure 3. The enthalpic deformational energy now increases as the two proteins approach each other. In the limit of small bending angle $\alpha$, two adjacent bending proteins with $\alpha$ in the symmetric conformation have the same tension-induced binding energy reduction as a single protein with a double bending angle of $2\alpha$. The energy scale for the cooperativity is thus in general set by $\Delta E_{\text{enth}}$. The effective interaction potential is, then, always less than the single protein binding energy since proteins are expected to unbind when $\Delta E_{\text{enth}}$ spacing approaches $E^{(1)}(s)$.
Although it would appear as if the enthalpic cooperativity depends on temperature within the WLC model (see Eqs. 1 and 3), this is not the case: $\xi_P$ is inversely proportional to $k_B T$ (see Appendix A) so neither $\Delta E_{\text{enth}}$ nor $\xi(F)$ depend on $k_B T$. There is, however, a purely entropic contribution to the cooperativity that is explicitly dependent on $k_B T$. In Appendix B, we obtain the following expression for the entropic correction to the cooperativity:

$$\Delta E_{\text{ent}}^{(2)} = k_B T \left\{ \frac{d}{\xi(F)} - \ln \left( 1 + \frac{d}{\xi(F)} + \frac{1}{4} \left( \frac{d}{\xi(F)} \right)^2 \left[ 1 - e^{-\frac{2d}{\xi(F)}} \right] \right) \right\}$$

(4)

for two proteins of length $d$ separated by a distance $l = |s_1 - s_2|$. The entropic contribution does not depend on the bending angle $\alpha$ and is the same for the symmetric and antisymmetric configurations. In the limit of protein separations that are large compared to the tension length $\xi(F)$, the entropic contribution $\Delta E_{\text{entr}} = \frac{1}{2} \Delta E_{\text{ent}}^{(2)}(\infty)$ to the single-protein binding energy is:

$$\Delta E_{\text{entr}} = k_B T \left\{ \frac{d}{2\xi(F)} - \ln \left( 1 + \frac{d}{2\xi(F)} \right) \right\}$$

(5)

This is, again, a negative quantity: the local constraints imposed on the DNA chain by the two binding proteins lowers the entropy of the complex as compared to a free chain and hence reduces the binding energy. The difference can, again, be interpreted as an effective entropic potential energy of interaction, which is now entropic. It is given by

$$V_{\text{entr}}(l) = k_B T \ln \left( 1 - \frac{\left( \frac{d}{\xi(F)} \right)^2 e^{-\frac{2d}{\xi(F)}}}{4 \left( 1 + \frac{d}{2\xi(F)} \right)^2} \right)$$

(6)

This effective entropic potential energy is always attractive. In Fig. 4 we show the entropic potential energy for two proteins of size $d$ equal to 20 Ångstroms and for a one pN applied tension ($\xi(F = 1\text{pN}) = 70$ Å).

For larger bending angles, the entropic interaction is both weaker and shorter in range than the enthalpic interaction. However, since this interaction does not depend on the magnitude of the bending angle, it dominates for zero bending angles, or bending angles that are very small. An interesting special case concerns the entropic interaction between two long strings of binding proteins. If we model a polymerized string of proteins bound to DNA
as a rigid section of size $d$, with $d$ assumed large compared to the tension length, and with zero total bending angle, then two such strings are expected to have an effective entropic interaction potential given by:

$$V_{\text{ent}}(l) \cong k_B T \ln \left( 1 - e^{-\frac{d}{\xi(F)}} \right)$$

$$d/\xi(F) \to \infty$$  \hspace{1cm} (7)

The free energy of two long rigid strings separated by a small gap is lowered by an amount of order $k_B T$ if the intervening gap is filled in either by shifting one of the two strings to close the gap or by adding additional binding proteins inside the gap. This effect provide us with a curious entropic stabilization of mechanism of polymerization of proteins along DNA strands.

When we increase the bending angle beyond $\pi/2$, new physical effects appear. As shown in Figures 5 and 6, there are in general two possible configurations for a symmetric two protein/DNA complex. Up to now, it has been tacitly assumed that the “S” or “stretched” configuration was the appropriate one (as shown in Fig.1) and indeed the S configuration has the lower free energy for bending angles $\alpha$ less than $\pi/2$. However, when the bending angle exceeds $\pi/2$ this is no longer the case. For low tensions, the “L”, or “looped” configuration has in fact the lower elastic free energy while for higher tensions, the S configuration is more stable. The two regimes are separated by a mathematical singularity which has the character of a first-order phase transition. In Fig. 7 we show the extension, $X$, of the two-kink configuration for which the kink angle is greater than $\pi/2$, as a function of tension, $F$. There is a transition from the L to the S configuration with increasing tension visible as a discontinuity of the extension at the transition point. There is no transition in the antisymmetric case.

In summary, we have shown that, within the confines of the WLC model, tension can trigger cooperative binding for anti-symmetrically arranged architectural proteins. The binding strength has both an enthalpic and an entropic contribution, and it has an appreciable magnitude for tensions of the order of one pN or higher. For larger bending angles, we find two competing configurations connected by a tension-induced phase-transition. Both the enthalpic and entropic contributions to cooperativity vanish in the limit of

\footnote{Formally, there is a divergence in Eq. 7 for small spacings $l$, but Eq. 7 should, of course, not be expected to retain validity when $l$ approaches a base-pair spacing.}
zero tension (see Eqs. 1 and 6). This last result is certainly not self-evident. The decrease in chain entropy imposed by two rigid sections can, for instance, be expected to depend on the spacing, even for zero tension. Interestingly, a study of the interaction between two stiff inclusions inside a two dimensional surface (such as a membrane) reports [Bruinsma, et al., 1994] that in this case there is a long-range zero-tension interaction with both entropic and enthalpic contributions, both dropping off as the inverse fourth power of the spacing between the inclusions. The disappearance of tension-induced cooperativity at \( F = 0 \) thus must be related to the fact that we are dealing with a one-dimensional geometry.

Experimental in vitro tests of the proposed mechanism can be performed by preparing a bundle of DNA strands, each strand containing bacterial gene operator sequences periodically spaced by a distance of \( l \) base pairs. The associated repressor protein (such as the lac repressor) binding specifically to the operator sites would induce local kinks at the operator sites. According to the model, the logarithm of the equilibrium repressor-operator binding constant \( K_{RO} \) contains a contribution that depends on the operator spacing \( l \) and the tension \( F \) of the DNA bundle according to Eq. 1.

A study of the kinetics of cooperative protein-DNA association can also be a testing ground. For instance, since the TATA box binding protein TBP is known to produce a large bending angle, the one-dimensional diffusion along the DNA of other proteins required for the RNA polymerase initiation complex, such as TFIIE, H and J, that are non-specifically bound to DNA will be speeded up by bending-induced cooperativity. The reason is that the effective potential \( \Delta V(l) \) turns the random one-dimensional diffusion into a directed process. It should be noted here that the weaker non-specific binding of DNA associating proteins will not deform the DNA strand as much as specific binding. However, studies of the dependence of non-specifically bound 434 repressors on the DNA flexibility indicate that non-specific bonding also involves distortions of the local DNA structure, so there still ought to be a tension-controlled interaction between specific and non-specifically bound proteins [Hogan and Austin, 1987]. We thus predict that (modest) tension will actually increase the formation rate of the RNA polymerase initiation complex. At high tension levels, the formation rate will decrease with tension for reasons discussed earlier.

Another possible area where the present theory could be applied is histone-DNA interactions. According to our model calculations, a collection of
non-specifically bound proteins ought to adopt an antisymmetric zig-zag configuration under tension. The binding of histones to DNA is reported to produce a zig-zag nucleosome structure consistent with our calculations [Thoma, et al, 1979]. Under tension, the zig-zag structure should thus be stabilized. It should be kept in mind, though, that the intervening linker histones may well affect the competition between different configurations [Thoma, et al, 1979].

An important question for the relevance of the work presented here is whether DNA is under tension under in-vivo conditions. DNA strands in suspended in good solvent are in fact not under tension. We believe that this is an exceptional case. A DNA strand whose ends are fixed is, even for low extensions, typically under a tension in the range of 0.01 pN due to thermal fluctuations, as shown by the micromechanical studies [Bustamante, et al, 1994, Bensimon, et al, 1994]. For extensions closer to one, the tension can be much larger. If a DNA strand is subject to the activity of force-transducing proteins—for instance during mitosis, RNA transcription, or homologous recombination—then much higher tensions can be generated. It is known that a single motor protein is able to generate a force of 10 pN or more [Yin, et al, 1995]. Finally, architectural proteins themselves generate tension if they attach to a DNA strand with fixed ends. When an architectural protein attaches, DNA material is required to accommodate the deformation of the DNA chain near the protein. A simple calculation shows that the self-induced tension of a DNA strand of length $L$ whose ends are held fixed a distance $X$ apart and which contains a line density $\rho$ of bending proteins is given by:

$$F \simeq \frac{4k_B T \langle \alpha^2 \rangle \xi_p}{\left(1 - \frac{X}{L}\right)^2} \rho^2$$

with $\langle \alpha^2 \rangle$ the average of the square of the bending angle. If the line density is of the order of one protein per hundred Angstrom and if $\langle \alpha^2 \rangle$ is of the order one, then this self-generated tension is of the order one pN (it should be possible to verify Eq. 8 in micro-mechanical measurements). It thus seems reasonable to assume that DNA is under tension for in-vivo conditions.

Our results were derived with DNA-protein binding in mind, but the general aspects of our conclusions are related to work in other areas. We can consider the predicted aggregation of proteins under tension as a form of stress-induced decomposition. Stress-induced phase-separation of multi-component
systems is actually a classic phenomenon in solid-state materials for the case that different constituents have different elastic moduli [Cahn, 1961], just as envisioned in the present case.

We conclude by noting that a number of technical objections can be raised against the method used in our study. It is not really reasonable to assume that DNA twist plays no role, in view of the helical nature of DNA, and that we can be allowed to restrict ourselves to a purely two-dimensional arrangement. However, it is our current belief that the introduction of the twist degree of freedom introduces qualitative, but not quantitative, modifications to the results reported here. The assumption of internal structural rigidity of proteins also is questionable. For instance, it is well known that many enzymes can undergo stress-induced structural changes. Enzymes bound to DNA also may change their structure under stress. Finally, it must be kept in mind that the WLC model neglects the possible influences of intervening structures, such as other bound proteins, on the tension-induced interaction between two bound proteins, and that looping and other manifestations of DNA self-interaction are ignored. Despite all these caveats, we feel that the basic result—stress-induced aggregation of DNA-bound proteins—is robust and should remain present in more realistic models.

Acknowledgements

We would like to thank C. Bustamante, D. Chatenay, and E. Siggia for helpful conversations. We are especially grateful to P. O’Lague for useful comments. R. B. acknowledges the support of the NSF through grant DMR-9708646.

Appendix A

We model the DNA strand as a rod that is free to move in two dimensions. The shape of the rod is parameterized in terms of an angular variable θ, which will vary with distance, s, along the rod. This parameterization is pictured in Figure 8. The energy of a configuration of the system is given by the following expression.

\[ H[\theta(s)] = \int ds \left( \frac{K}{2} \left( \frac{d\theta}{ds} \right)^2 - F \cos \theta \right) \]

(A.1)
The rigidity against bending is parameterized in terms of a stiffness parameter $K$, while $F$ is the tension applied to the rod. The quantities referred to in the text are related to $K$ and $F$ by $\xi (F) = \sqrt{K/F}$ and $\xi_p = K/k_B T$. In the “classical” limit, which applies at very low temperatures, is determined by the extremum equation

$$\frac{\delta H}{\delta \theta (s)} = -K \frac{d^2 \theta}{ds^2} + F \sin \theta (s) = 0$$  \hspace{1cm} (A.2)

This equation is solved by quadratures by noting that it is identical to the first order differential equation

$$\frac{K}{2} \left( \frac{d\theta (s)}{ds} \right)^2 + F \cos \theta (s) = \kappa$$  \hspace{1cm} (A.3)

with $\kappa$ a constant. From Eq. (A.3) we immediately obtain

$$\frac{d\theta}{\sqrt{\frac{2F}{K} (\Lambda - \cos \theta)}} = \pm ds$$  \hspace{1cm} (A.4)

with $\Lambda$ another constant. Integration of (A.4) yields an implicit form for $\theta(s)$, in which $s$ is represented as a function of $\theta$. The specific function is a combination of elliptic integrals. There is no evident way to invert the expression thus derived to obtain $\theta$ as an explicit function of $s$.

On the other hand, when the bending of the DNA is small, so that $\theta$ is small, the cosine function in (A.1) can be expanded. The zeroth order term is a constant, “background” energy. The energy of the system, as it depends on the configuration of the DNA, is given by

$$H [\theta (s)] = \int ds \left\{ \frac{K}{2} \left( \frac{d\theta (s)}{ds} \right)^2 + \frac{F}{2} \theta (s)^2 \right\}$$  \hspace{1cm} (A.5)

The statistical mechanics of the system controlled by this energy can be analyzed in complete detail. Here, the extremum equation is

$$-K \frac{d^2 \theta (s)}{ds^2} + F \theta (s) = 0$$  \hspace{1cm} (A.6)

the solution of which is

$$\theta (s) = Ae^{s/\xi (F)} + Be^{-s/\xi (F)}$$  \hspace{1cm} (A.7)
Where $\xi (F) = \sqrt{KF} \equiv \sqrt{\xi_p k_B T F}$, and $A$ and $B$ are constants.

As an example of the use of the small angle formulas A.5-A.7 we calculate the free energy cost of the presence of two proteins that kink the DNA to which they are attached. These insertions enforce a discontinuity in $d \theta / ds$ at the location of each kink. We assume that the magnitude of the discontinuity is $\alpha_-$ at the first kink and $\alpha_+$ at the second. To simplify the analysis, we place the first kink at $s = -l/2$ and the second kink at $s = l/2$. The calculation of the classical solution subject to these constraints is relatively straightforward. One finds

$$
\theta (s) = \begin{cases} 
  \theta_- e^{\sqrt{FK}(s + \frac{l}{2})} & s < -\frac{l}{2} \\
  -\theta_+ \frac{\sinh \sqrt{FK}(s - \frac{l}{2})}{\sinh \sqrt{FK}l} + \theta_+ \frac{\sinh \sqrt{FK}(s + \frac{l}{2})}{\sinh \sqrt{FK}l} & -\frac{l}{2} < s < \frac{l}{2} \\
  \theta_+ e^{-\sqrt{FK}(s - \frac{l}{2})} & \frac{l}{2} < s \end{cases}
$$

(A.8)

According to (A.8), the angle is equal to $\theta_-$ immediately to the right of $s = -l/2$ and $\theta_+$ immediately to the left of $s = -l/2$. By the same token $\theta(l/2 - \epsilon) = \theta_+$ and $\theta(l/2 + \epsilon) = \theta_+$. The kinks give rise to a discontinuity at $s = \pm l/2$, which means that $\theta_\neq \theta_- \neq \theta_+$. We write

$$
\theta_- = \theta_+ - \alpha_- \\
\theta_+ = \theta_+ + \alpha_+
$$

(A.9)

Then, the total energy, $E$, of the bent rod, as given by Eqs. A.5, A.8 and A.9, is given by

$$
E = \frac{1}{2} \sqrt{FK} \left\{ (\theta_- - \alpha_-)^2 + (\theta_+ + \alpha_+)^2 + \theta_+^2 \coth \sqrt{FK}l + \theta_-^2 \coth \sqrt{FK}l + \frac{2\theta_+ \theta_-}{\sinh \sqrt{FK}l} \right\}
$$

(A.10)

If we replace $\theta_+$ by $\Sigma + \Delta$ and $\theta_-$ by $\Sigma - \Delta$, then Eq. A.10 becomes

$$
E (\Sigma, \Delta) = \sqrt{FK} \left\{ \Sigma^2 e^{\sqrt{FK}l + \frac{l}{\sinh \sqrt{FK}l}} + \Delta^2 e^{-\sqrt{FK}l - \frac{l}{\sinh \sqrt{FK}l}} + \Sigma (\alpha_+ - \alpha_-) + \Delta (\alpha_+ + \alpha_-) + \alpha_+^2 + \alpha_-^2 \right\}
$$

(A.11)
The partition function, $Z$, of the system is given by

$$Z = \int \int d\Sigma d\Delta \exp (-\beta E(\Sigma, \Delta))$$

(A.12)

where $\beta = 1/k_B T$. This double gaussian integral is evaluated by completing squares. Taking the log and multiplying by $k_B T$ to obtain the free energy, $F$, we find

$$F = \frac{\sqrt{FK}}{4} \left\{ \alpha_+^2 + \alpha_-^2 + 2 \alpha_+ \alpha_- e^{-\sqrt{FK}} \right\} - \frac{k_B T}{2} \ln \left( 1 - e^{-2\sqrt{FK}} \right)$$

(A.13)

The first term on the right hand side of the expression for the free energy in Eq. (A.13) is the mean field approximation to the free energy cost of two kinks in the rod. The second term is a partial contribution to the free energy due to fluctuations, in particular fluctuations in the angles $\theta_+$ and $\theta_-$. To complete the evaluation of the free energy associated with a pair of kinks, we must now average over all other fluctuations in the rod. To do this, we expand $\theta(s)$ in normal sinousoidal modes, subject to the condition that those modes do not alter the values of $\theta$ immediately to the right or the left of the locations of the kinks. The contribution to the free energy that depends on the distance, $l$, between the kinks arises from the fluctuations in that region. This fluctuation sum reduces to

$$k_B T \left\{ \sum_{n=1}^{\infty} \ln \left[ \left( \frac{n\pi}{l} \right)^2 + \frac{F}{K} \right] + \frac{1}{2} \ln \frac{F}{K} \right\} = \frac{k_B T}{2} \ln \left( 1 - e^{-\sqrt{FK}} \right)$$

(A.14)

In arriving at the expression on the right hand side of Eq. (A.14), an infinite contribution to the sum over logarithms was subtracted off. This “regularization” of the sum is consistent with standard field theoretical approaches to the evaluation of the free energy of systems such as the one under consideration here. The right hand side of (A.14) exactly cancels the fluctuation contribution to (A.13). Thus, the free energy of the two-kink system consists entirely of the mean-field contribution.

**Appendix B**

In the limit that the kinks occupy an infinitesimal portion of the DNA, the free energy cost of a pair of them is, as noted in the appendix above, given
entirely by mean-field theory. There is a mechanism leading to fluctuation induced interaction energy, and that is the modification of the bending modulus by the proteins that cause the kinks. This modification can be modeled as follows. In the small-angle approximation, one replaces the energy expression in A.5 by

$$H[\theta(s)] = \int ds \left\{ \frac{K_{1,2}}{2} \left( \frac{d\theta(s)}{ds} \right)^2 + \frac{F}{2} \theta(s)^2 \right\}$$

where the symbol $K_{1,2}$ stands for the two possible values, $K_1$ and $K_2$, that the bending modulus can now take on in the various regions. The subscript 2 applies in the regions that are in the immediate vicinity of the proteins, while the subscript 1 is appropriate everywhere else. This means that $K_1$ is the unsubscripted $K$ in previous expressions. The effects of modifications of the bending modulus can be calculated separately from the consequences of the bending of the DNA by proteins. This means that we can ignore any discontinuities or alterations of the equilibrium value angle $\theta(s)$ that result from the presence of proteins.

The regions in which the bending modulus takes on its two possible values are indicated in Figure 8. The bending modulus is equal to $K_2$ in the two heavily drawn regions, while it is equal to $K_1$ everywhere else. Matching conditions at the boundary between regions are that $\theta(s)$ and $K_i d\theta/ds$ are continuous.

In order to evaluate the contribution of fluctuations, it is necessary to determine the eigenfunctions of the Hamiltonian B.1. One searches for solutions to the equation

$$-K_{1,2} \frac{d^2 \theta(s)}{ds^2} + F\theta(s) = \lambda\theta(s)$$

There will be two sorts of solution: even and odd.

**Even solutions**

These solutions have the form

$$\theta(s) = \begin{cases} 
\cosh q_1 s & 0 < s < l/2 \\
A \cosh q_2 (s - l/2) + B \sinh q_2 (s - l/2) & l/2 < s < l/2 + d \\
C \cosh q_1 (s - l/2 - d) + D \sinh q_1 (s - l/2 - d) & l/2 + d < s
\end{cases}$$

(B.3)
where \( \theta_o(-s) = \theta_o(s) \).

Here
\[
q_1 = \sqrt{(F - \lambda)/K_1}
\]  
(B.4)

and
\[
q_2 = \sqrt{(F - \lambda)/K_2} = q_1 \sqrt{\frac{K_1}{K_2}}
\]  
(B.5)

Making use of the boundary conditions, we find

\[
A = \cosh q_1 l/2 
\]  
(B.6)

\[
B = \sqrt{\frac{K_1}{K_2}} \sinh q_1 l/2
\]  
(B.7)

\[
C = \cosh q_1 l/2 \cosh q_2 d + \sqrt{\frac{K_1}{K_2}} \sinh q_1 l/2 \sinh q_2 d
\]  
(B.8)

\[
D = \sqrt{\frac{K_2}{K_1}} \cosh q_1 l/2 \sinh q_2 d + \sinh q_1 l/2 \cosh q_2 d
\]  
(B.9)

**Odd solutions**

Here, the solutions are

\[
\theta(s) = \begin{cases} 
\sinh q_1 s & 0 < s < l/2 \\
A \cosh q_2 (s - l/2) + B \sinh q_2 (s - l/2) & 1/2 < s < l/2 + d \\
C \cosh q_1 (s - l/2 - d) + D \sinh q_1 (s - l/2 - d) & l/2 + d < s 
\end{cases}
\]  
(B.10)

where \( \theta_o(-s) = -\theta_o(s) \), and, in this case, the coefficients are given by

\[
A = \sinh q_1 l/2 
\]  
(B.11)

\[
B = \sqrt{\frac{K_1}{K_2}} \cosh q_1 l/2
\]  
(B.12)

\[
C = \sinh q_1 l/2 \cosh q_2 d + \sqrt{\frac{K_1}{K_2}} \cosh q_1 l/2 \sinh q_2 d
\]  
(B.13)

\[
D = \sqrt{\frac{K_2}{K_1}} \sinh q_1 l/2 \sinh q_2 d + \cosh q_1 l/2 \cosh q_2 d
\]  
(B.14)

The ultimate goal of the calculation is the so-called Fredholm determinant of the differential operator on the right hand side of Eq. B.2. This
determinant is readily evaluated with the use of a by-now well-known trick [Coleman, 1985]. The trick yields the following expression for the contribution to the free energy of fluctuations in $\theta(s)$.

$$A = \frac{k_B T}{2} \ln (\theta_e (L) \theta_o (L)) \quad (B.15)$$

where the arguments of the logarithm are the even and odd solutions displayed in (B.3) and (B.10), where $\lambda$ has been set equal to 0. There are, in addition, normalization factors. The factor that multiplies the even solution sets the magnitude of that solution equal to one at $s = 0$. The factor multiplying the odd solution sets the slope of that solution equal to unity at the origin. The argument $L$ is the total length of the segment to which the proteins are attached. In the following development, the limit $L \to \infty$ is taken, and the contribution to the free energy relevant to the interaction between the two attached proteins is extracted.

In the limit of asymptotically large $L$ the two factors in the argument of the logarithm in Eq. (B.13) are

$$e^{-q_1 d} \left\{ \cosh q_2 d + \sinh q_2 d \left[ \sqrt{\frac{K_1}{K_2}} \frac{1 + e^{-q_1 l}}{2} + \sqrt{\frac{K_2}{K_1}} \frac{1 - e^{-q_1 l}}{2} \right] \right\} \quad (B.16)$$

and

$$e^{-q_1 d} \left\{ \cosh q_2 d + \sinh q_2 d \left[ \sqrt{\frac{K_1}{K_2}} \frac{1 - e^{-q_1 l}}{2} + \sqrt{\frac{K_2}{K_1}} \frac{1 + e^{-q_1 l}}{2} \right] \right\} \quad (B.17)$$

After some algebra we find for the dependence of the free energy of the system on the parameters $l$, $d$, and the $K_i$’s

$$A = \frac{k_B T}{2} \ln (f) \quad (B.18)$$

where

$$f = e^{2(q_2 - q_1)d} + \frac{e^{-2q_1 l} \sinh 2q_2 d \left( \sqrt{K_1} - \sqrt{K_2} \right)^2}{\sqrt{K_1 K_2}}$$

$$+ \frac{e^{-2q_1 l} \sinh^2 q_2 d \left( K_1 - K_2 \right)^2}{4 K_1 K_2} \left[ 1 - e^{-2q_1 l} \right] \quad (B.19)$$

Note that the dependence of the argument of the logarithm on the separation, $l$, between the two regions of differing stiffness constant is as $A - Be^{-2q_1 l}$. This implies an always attractive interaction.
Table 1

Enthalpic energy of interaction

| $F$(pN) | $\xi(F)$ | $V_{\text{enth}}(l = 0 \text{ Å})$ | $V_{\text{enth}}(l = 50 \text{ Å})$ |
|---------|-----------|-----------------------------------|-----------------------------------|
| 0.1     | 221 Å    | 0.82                              | 0.66                              |
| 1.0     | 70 Å     | 2.6                               | 1.27                              |
| 10      | 22 Å     | 8.2                               | 0.85                              |

Table of the enthalpic interaction strength, as given by the last term on the right hand side of Eq. (1), for physically reasonable values of the temperature, the persistence length $\xi_p$, and the tension, $F$. For the dependence of the binding cooperativity range, $\xi(F)$ on tension and other parameters, see Eq. (2).

Figure 1: Strand of DNA containing two proteins. The proteins induce “kinking” on the DNA strand. Illustrated are the case of antisymmetric and symmetric configurations of the two bound proteins. The distance between proteins is expressed in terms of the locations, \( s_1 \) and \( s_2 \), of each of them on the strand.

Figure 2: The attractive interaction for an antisymmetrically oriented pair of bound proteins. Plotted is the total energy of the configuration in units of \( k_B T \), multiplied by the ratio \( \xi(F)/\xi_p \), where \( \xi(F) \) is the tension-dependent length scale, defined in Eq. 3 and \( \xi_p \) is the persistence length of the DNA strand. Curves are displayed for various values of the “kink angle”, \( \alpha \), as shown in Figure 1.

Figure 3: The repulsive interaction between two proteins bound in a symmetric configuration. Plotted is the total energy of the configuration in units of \( k_B T \), multiplied by the ratio \( \xi(F)/\xi_p \), where \( \xi(F) \) is the tension-dependent length scale, defined in Eq. 3 and \( \xi_p \) is the persistence length of the DNA strand. Curves are displayed for various values of the “kink angle”, \( \alpha \), as shown in Figure 1.

Figure 4: The entropic interaction potential between two identical bound proteins resulting from the effect of each of them on the bending modulus of the strand of DNA to which they are attached. The interaction is plotted in units of \( k_B T \) under the assumption that the region of affected DNA is 70 Ålong, and that the applied tension is 1 pN.

Figure 5: The “loop” or L configuration of two symmetrically bound proteins, when the bend angle enforced by a bound protein is greater than \( \pi/2 \). This is the preferred configuration when the applied tension is small.

Figure 6: The stretched, or S configuration of two symmetrically bound proteins, when the bend angle exceeds \( \pi/2 \). This is the preferred configuration at high levels of applied tension.
Figure 7: The overall extension of a very long strand of DNA containing two identical symmetrically bound proteins, the bend angle, $\alpha$, of each of which is equal to 2.1. The extension, $X$, is relative to the fully extended DNA strand, measured in units of $(2K/F)^{1/2}$, where $F$ is the applied tension and $K$ is the bending modulus. The vertical axis is the applied tension in units of $K/2L^2$ where $L$ is the distance along the DNA backbone between proteins along the DNA strand. See Appendix A for a full discussion of the parameters utilized.

Figure 8: The parameters in Eq. A.1. The quantity $\theta(s)$ is the angle between the flexible strand and the horizontal axis, while $s$ is arclength.

Figure 9: The regions of varying stiffness in a strand containing two bound proteins that alter the bending modulus where they attach to a strand of DNA. The values that the bending modulus, $K$, takes in the various regions are indicated. See Eq. B.1 and surrounding text in Appendix B.
