ABSTRACT
Hyponatremia prolongs hospital stay and hypernatremia better predicts mortality than hyponatremia in hospitalized patients with community-acquired pneumonia

Introduction: Dysnatremia is reported to have a prognostic effect in various diseases. A limited number of studies have been published on dysnatremia-related parameters and clinical outcome in patients with pneumonia. The aim of the study is to analyze the factors related to baseline dysnatremia and to evaluate the clinical outcome of dysnatremia on hospital stay, 30-day and 1-year mortality in hospitalized patients with community-acquired pneumonia (CAP).

Materials and Methods: The study is a two-centre, retrospective, cross-sectional study. According to the baseline corrected sodium values, hospitalized patients with CAP were grouped as hyponatremia (< 135 mmol/L), normonatremia (135-145 mmol/L) and hypernatremia (> 145 mmol/L).

Results: Of all the 471 patients included, 119 (25.3%) had hyponatremia and 25 (5.3%) had hypernatremia. Higher leucocytes and lower albumin values correlated with hyponatremia while female gender, higher leucocytes and urea levels correlated with hypernatremia. Baseline hypernatremia prolonged hospital stay (9.2 ± 5.6, vs. 7.5 ± 4.6, respectively, p= 0.001) and increased 1-year mortality. On the other hand, hypernatremia predicted 30-day (40%, vs. 10%, p< 0.001) and independently predicted 1-year mortality (p< 0.001).
Conclusion: In hospitalized patients with CAP, baseline hyponatremia prolongs hospital stay while hypernatremia signals a worse outcome both in the short term and long term.

Key words: Charlson comorbidity index; glucose; hyponatremia; hypernatremia

INTRODUCTION

Community-acquired pneumonia (CAP) is a common serious health problem, being the second most common cause of hospitalization and the most common infectious etiology of mortality worldwide (1,2).

Presence of dysnatremia is described as a determinant of mortality in various studies (3,4). Sodium is the main factor to determine plasma osmolality and sodium disturbance is among the most common laboratory abnormalities in clinical practice (5). The kidney and thirst center of the hypothalamus play the major role in sodium regulation. Skin and other tissues may accumulate sodium. Sodium disturbance may be caused by advanced age, drugs, comorbidities and hydration status (4). Hypernatremia is mainly developed by decreased total body water through insensible losses and sepsis. In hypernatremia, plasma osmolality increases mediating with water efflux and cell shrinkage. Import of the ions trigger organic osmolyte accumulation and due to intracellular molecular crowding, cellular reactive oxygen species and cytokines; cell damage continues (6). Hyponatremia may be seen in malignancies, infections or as a drug side effect. It results mainly from non-osmotic vasopressin activity (7). Hyponatremia and hypernatremia may result with altered mental status and coma (8).

In current guidelines of CAP, hyponatremia is one of the criteria in pneumonia severity index whereas hypernatremia is not specified (9). Only few studies have analyzed the predictive factors for dysnatremia in patients with CAP. Older age, higher Charlson comorbidity index (CCI) scores, baseline leucocytes and C-reactive protein (CRP) levels were described as predictors of hyponatremia (10-12). Fewer studies have focused on hypernatremia-related parameters regarding the patients treated in nonspecific units and septic intensive care unit (ICU). Advanced age, co-morbidities, lower estimated glomerular filtration rate and acute physiology and chronic health evaluation II scores are claimed to increase the risk of hypernatremia (4,13,14).

Short-term mortality is reported higher in patients with hyponatremia in a number of studies with different study designs (3,15-19). The presence of a U-shaped association between the degree of hyponatremia and mortality risk is a controversial issue (15,16,18). In contrast with these studies, in-hospital mortality was reported not to be related to hyponatremia in another study (11).

Hypernatremia is a rare laboratory abnormality and if present, it increases mortality in overall hospital admissions (13,14,20-22). A limited number of studies including CAP patients have also described higher
mortality in hypernatremia (12). The literature demonstrates a scarcity of search results on the predictive analysis of dysnatremia regarding the long-term outcome of CAP patients (12).

In present study, correlative factors for baseline dysnatremia in hospitalised patients with CAP were investigated. The predictive value of both hyponatremia and hypernatremia for the length of hospital stay (LOS) and both short- and long-term mortality were analyzed.

MATERIALS and METHODS

The present study is a two-centre, retrospective, designed in a chest diseases clinic at a state hospital (Center 1) and a training and research hospital (Center 2).

This study is derived from two centers in two discrete cities. In the city of the first center, there are two specialized clinics and our study includes the larger of these (the center with the 30-bed capacity). The city of the second center is a very populous city and the study includes mainly a sublinic (with a 34-bed capacity) of a large center.

Inclusion of the Patients

A hospital database system search was conducted via International Classification of Diseases, 10th version codes of J18 (pneumonia) among hospitalized patients between January 2017 and January 2018. All patients’ clinical files were investigated to verify a diagnosis of CAP. Hospital-acquired pneumonia, ICU-transferred patients, patients without recorded baseline sodium levels were excluded (Figure 1).

The study was performed in accordance with relevant ethical principles of Helsinki Declaration and

Figure 1. Flowchart of the patient inclusion.
CAP: Community-acquired pneumonia, ICD: International classification of diseases, ICU: Intensive care unit.
approved by the ethics committee of Canakkale Onsekiz Mart University (2011-KAEK-27/2019-1900067286). Written informed consent was not obtained from the patients due to the retrospective design of the study.

Definitions

**CAP:** Compatible symptoms (cough, sputum, shortness of breath), physical examination findings and imaging findings on chest X-ray or thorax computerized tomography (CT) (9).

**Dysnatremia:** Serum sodium levels out of range 135-145 mmol/L. **Hyponatremia:** a baseline serum sodium concentration of < 135 mmol/L, severe hyponatremia: a baseline serum sodium concentration of < 130 mmol/L. **Hypernatremia:** a baseline serum sodium level of > 145 mmol/L (23).

Data Collection

Age, gender, complaints (shortness of breath, cough, sputum, fever, chest pain, hemoptysis), co-morbid diseases, baseline complete blood count parameters of leucocytes (/µL), hemoglobin (g/dL), platelet (/µL), neutrophils (/µL) and lymphocytes (/µL), CRP (mg/L), glucose (mg/dL), blood urea nitrogen (BUN) (mg/dL), albumin (g/dL) and sodium (mEq/L) levels were recorded. To correct sodium levels, each 100 mg/dL increment in glucose levels higher than 100 mg/dL, sodium levels were adjusted upward by 2 mEq/L (13).

Neutrophils to lymphocytes ratio (NLR) and CCI scores were calculated (24).

Study Design

Baseline sodium levels were classified as hyponatremia, normonatremia and hypernatremia. Demographics, baseline laboratory values of hyponatremic and normonatremic patients as well as of hypernatremic and normonatremic patients were compared.

Outcome measures were length of hospital stay (LOS), one-month mortality and 1-year mortality according to baseline sodium levels.

Mortality was questioned via National Death Database (www.obs.gov.tr).

Statistical Analysis

All statistical analyses were conducted using a statistical software package (SPSS for Windows, version 16.0; SPSS Inc.; Chicago, IL, USA). Quantitative data are expressed as mean ± standard deviation (SD) and qualitative data are expressed as frequencies. Independent sample t-test was used for the comparison of averages and chi-square test was used for the categorical variables. Logistic regression test was used for independent predictors of hyponatremia. Cox-regression analysis was used for multivariable analysis of one-year independent predictors of mortality. A p value of ≤ 0.05 was considered to be significant.

RESULTS

Of all the 471 patients included, the mean age was 66 ± 18 years and 313 (67%) were male. Complaints at presentation were shortness of breath (n= 368, 78%), cough (n= 354, 75%), sputum (n= 282, 60%), fever (n= 177, 38%), weakness, (n= 78, 17%) and general condition impairment (n= 21, 5%). The most frequent co-morbidities were chronic obstructive pulmonary disease or asthma (n= 205, 44%), congestive heart failure (n= 79, 15%), diabetes mellitus (n= 94, 20%), malignancy (n= 66, 14%), coronary artery disease (n= 63, 13%), serebrovascular disease (n= 63, 14%), connective tissue disease (n= 9, 2%) and chronic renal failure (n= 30, 6%). The average CCI score was 3.8 ± 2.1 (0-10). Baseline sodium values were classified as normonatremia in 327 (69.4%), hyponatremia in 119 (25.3%) and hypernatremia in 25 (5.3%) patients. Thirty-day, 90-day and 1-year mortality were seen in 56 (12%), 81 (17%) and 135 (29%) patients, respectively.

Comparison of hyponatremic and normonatremic patients revealed no difference between gender, age, presentation symptoms, NLR and platelets. Although hyponatremic patients had higher CCI scores, there was no statistical difference. In hyponatremia, patients had higher levels of leucocytes (p= 0.001) and CRP (p= 0.009). Albumin levels were significantly lower in hyponatremia (p< 0.001) (Table 1). In multivariable analysis, higher leucocytes and lower albumin levels were determined as independent predictors of hyponatremia (Table 2).

In hyponatremic patients, LOS was significantly longer (p= 0.001). In-hospital mortality was seen in 13 of hyponatremics (11%) and 32 (10%) of normonatremics (p= 0.724). In one-year, 42 (35%) of hyponatremics and 78 (24%) of normonatremics died (p= 0.035). Hyponatremia did not alter 30-day mortality while it increased one-year mortality. When levels of sodium were categorized, the lowest death rate was...
between the values of 135-140 mmol/L. Once the score of 140 mmol/L was passed, an increasing trend for mortality was observed (Figure 2).

Both hypernatremic and normonatremic patients exposed similar complaints. Hypernatremia was detected more frequently in females (p = 0.009) and at advanced age (p = 0.025). Hypernatremics had higher baseline leukocytes (p = 0.011) and urea levels (p < 0.001) (Table 3). Hospital stay did not differ between hypernatremia and normonatremia (p = 0.086). Thirty-day mortality was seen in 10 (40%) and 1-year mortality in 15 (60%) patients. Both short- and long-term mortality were significantly higher in hypernatremia.

Independent predictors for one-year mortality were higher CCI scores and the presence of hypernatremia (Table 4, Figure 3).

### DISCUSSION

The present study indicates that when compared to normonatremia; hypernatremia correlates with higher leukocytes and lower albumin while hypernatremia correlates with female gender, higher leukocytes and urea levels. To the best of our knowledge, the current study presents a systematic comparison between hypernatremic and normonatremic hospitalized CAP patients for the first time. The study also revealed that hypernatremia prolongs hospital stay and increases long-term mortality. Hypernatremia, on the other hand, increases mortality both in the short- and long-term. Hypernatremia predicts long-term mortality better than hyponatremia.

Hyponatremia is more frequent in pneumonia compared to the overall hospitalizations in internal med-
icine clinics. In general wards, the frequency of hyponatremia is reported as 12-15% (3,10,25). As for CAP, hyponatremia is described in 22-32% (4,12,17). The rate of hypernatremia differs according to the study unit. In neurologic ICU, baseline hypernatremia is reported as 13% (26). In patients with CAP, hypernatremia is determined in 1-3% (3,4,10,27). The present study has revealed a hyponatremia rate complies with, however a slightly higher hypernatremia rate. In most of the studies the sodium levels were not corrected based on glucose levels, which we believe, may be the reason of different findings. In line with this comment, Tsipotis et al. have put forward that after having corrected the baseline sodium levels a higher frequency of pneumonia and sepsis in hypernatremic patients have been reported (13). Furthermore, there may be a geographical and different microbiologic spectrum affecting the prevalence of dysnatremia. Novel research and studies may enlighten this issue.

Only few studies have analyzed the related parameters with hyponatremia. Older age and higher CCI scores have been referred to all-caused hyponatremia (10). In patients with CAP, leucocytes and CRP, older age and higher CCI scores were defined as correlative factors for hyponatremia (11,12). A current study all pneumonia, demographics were found similar whereas hyponatremic patients had more frequent malignancy, renal failure, and legionella infection (19). In present study, demographics and CCI scores were similar. Leucocytes and lower albumin levels best correlated with hyponatremia.

Various studies have marked a worse survival in hyponatremic patients with various diseases heart failure, severe liver disease and cancer (3,4,15-17,28,29). In liver disease and congestive heart failure, a U-shaped association between serum sodium level and mortality was emphasized (15,16). In the multicentre study of Krüger et al., both inpatients and outpatients with CAP demonstrated a U-shaped asso-
Serum sodium levels were not corrected in this study (12). A recent study by Müller et al. has defined similar ICU admission with higher in-hospital mortality in hyponatremic pneumonia (19). This study has included only patients with pneumonia admitted to emergency department. The cut-off value for hyponatremia was defined as 130 mmol/L and 7.7% of the patients had baseline hyponatremia. Also, all hospital-acquired and CAP patients were included and sodium levels were not recalculated. Contrary to these results, Zilberberg et al. did not find any relationship between in-hospital mortality and hyponatremia in patients with pneumonia (11). In line with this report, the present study did not reveal a relationship between one-month mortality and low sodium levels. In 2011, Chawla et al. analyzed the relationship between corrected hyponatremia and mortality in all-cause hospitalizations. A degree-related mortality with sodium levels was refused in the study and the authors concluded that decreased serum sodium reflects more severe underlying disease rather than causing the death itself (18). Similarly, in our study, CCI levels did not differ significantly between hypo- and normoneutremics and we infer that such lack of varying may be the reason of similar short-term outcome of these patients.

**Hospital Stay and Long-Term Outcome of Hyponatremia**

Only a limited number of studies have focused on hospital stay and hyponatremia. A recent study...
reported no relationship between sodium levels and hospital stay (19). In contrast, other studies have proved longer LOS in hyponatremia (4,17). Similar to these studies, duration of hospitalization is indicated to be longer in the current study. We think that, since the demographics and CCI scores are similar in these patients, longer LOS may be caused by higher baseline CRP levels as well as the treatment duration for correcting hyponatremia.

To our knowledge, only one study has investigated long-term outcome in hyponatremic CAP patients concluding higher long-term mortality with lower baseline sodium levels (4). In line with this study, we have found worse long-term survival in hyponatremic CAP patients.

Hypernatremia-related factors have been studied less frequently in the literature. Hypernatremic and normonatremic patients hospitalized in medical wards were investigated without a statistical comparison. The average age was higher and female gender (53% vs. 47%) was more frequent in hypernatremics. Co-morbidities were compared discretely and hypertension, congestive heart failure, renal failure and cerebrovascular disease were reported more frequent in hypernatremia (4). In all-cause hospitalizations, hospital-acquired hypernatremia is reported to be higher in advanced age, higher comorbidity index, lower estimated glomerular filtration rate (13). In septic ICU patients, acute physiology and chronic health evaluation II score is found to be associated with hypernatremia (14). The present study attests that hypernatremia is more frequent in females and advanced age. Higher baseline leucocytes and urea levels were found to be associated with hypernatremia. Due to the low number of hypernatremic patients, a logistic regression analysis was not performed. Further multi-centre studies may be required in this regard.

A uniform short- and long-term worse survival is reported in hypernatremia. In-hospital mortality is higher in hypernatremia in all-cause hospitalizations and pneumonia (3,4,13). Ates et al. have revealed a 49.5% mortality in severe hypernatremic patients admitted to emergency department (30). The mortality risk is described higher in hypernatremia than in hyponatremia in various studies (4,31). In present study, hypernatremic patients significantly less-survived than hypo- and normo-natremic patients. In parallel with the literature, long-term mortality is detected higher in hypernatremia in current study.

Hyponatremia and hospital acquired hypernatremia is found to increase hospital stay (4,13). The present study, however, did not yield such a significance, which we believe is caused by early in-hospital death.

The first limitation of the present study is the retrospective, two-centre study design. The second is that the microbiological pathogens were not studied widely. On the other hand, the strength of the study is that the study benefits from the inclusion of a homogenous study group from two large chest disease clinics. Furthermore, the values of sodium were corrected and both short- and long- term prognoses were investigated.

In conclusion, hyponatremia causes longer hospital duration of treatment and hypernatremia represents a higher mortality risk than hyponatremia in hospitalised patients with CAP. Appropriate treatment should be given in dysnatremia with closer medical examination. Further prospective studies along with microbiologic spectrum of pneumonia may determine more secure cut-off levels for sodium.
