Scalar fields, φi, can be coupled non-minimally to curvature and satisfy the general criteria: (i) the theory has no mass input parameters, including Mp = 0; (ii) the φi have arbitrary values and gradients, but undergo a general expansion and relaxation to constant values that satisfy a nontrivial constraint, K(φi) = constant; (iii) this constraint breaks scale symmetry spontaneously, and the Planck mass is dynamically generated; (iv) there can be adequate inflation associated with slow roll in a scale invariant potential subject to the constraint; (v) the final vacuum can have a small to vanishing cosmological constant (vi) large hierarchies in VEV’s can naturally form; (vii) there is a harmless dilaton which naturally eludes the usual constraints on massless scalars. These models are governed by a global Weyl scale symmetry and its conserved current, Kμ. At the quantum level the Weyl scale symmetry can be maintained by an invariant specification of renormalized quantities.

I. INTRODUCTION

There has recently been considerable interest in scale symmetric general relativity, in conjunction with inflation and dynamically generated mass scales [1–13]. This is a theory containing fundamental scalar fields together with general covariance and non-minimal coupling of the scalars to curvature, but no Planck mass. Remarkably, starting with a scale invariant action, it is possible to spontaneously generate the Planck mass itself and naturally produce significant inflation. The inflation can, moreover, lead to large hierarchies of scalar vacuum expectation values (VEV’s). All of this occurs as one unified phenomenon.

The key ingredient of this mechanism is a global Weyl scale symmetry and its current, Kμ. Gravity drives the scale current density, K0, to zero, much as any conserved current charge density dilutes to zero by general expansion. However, the particular structure of the Kμ current is such that it has a “kernel,” i.e., Kμ = ∂μK. Hence, as the scale charge density is diluted away, K0 → 0, the kernel evolves as K → constant. K is the order parameter that defines a spontaneous scale symmetry breaking and the Planck scale, K = O(Mp2). The breaking of scale symmetry here is “inertial,” and is determined by the random initial values of the field VEV’s that settle down to yield a random fixed value of K.

In the multi-field case the role of the potential is to determine the relative VEV’s of the scalar fields contributing to K. In this case the nonzero constant value of K defines a constraint on the scalar field VEV’s, requiring that the VEV’s lie on an ellipse in multi-scalar-field space. The inflationary slow-roll conditions are consistent with constant K and an inflationary era readily occurs in which the field VEV’s migrate along the ellipse, and ultimately flow to an infrared fixed point. For the special case that the potential has a flat direction the fixed point corresponds to the potential minimum, the field VEV’s flow to it, and the final cosmological constant vanishes.

In the present paper we discuss how this “current algebra” works in detail, and how inflation and Planck scale generation emerge from it. We will first illustrate this phenomenon in Section II, in a simplified theory with a single scalar field, φ, and a non-minimal coupling to gravity ∼ −(1/12)αφ2K. For us α < 0, and a nonzero VEV of φ induces a positive Planck (mass)2. We allow scale invariant potentials, such as λφ4. This theory thus has a global Weyl scale symmetry, and a conserved scale current:

\[ K_\mu = (1 - \alpha)\phi \partial_\mu \phi. \] (1)

The prefactor is relevant and nontrivial when we consider N scalar fields (this current vanishes in the α = 1 limit when the Weyl symmetry becomes local [7]).

The Weyl scale current kernel is, K = (1 − α)φ2/2. The kernel, K, is driven to a constant during an initial period of expansion of the universe, as K0 is diluted to zero. There is no ellipse in the single field case, and the field comes to rest with a fixed, eternal VEV, φ = \(\sqrt{2K/(1 - \alpha)}\). The theory acquires the Planck mass as Mp2 = −αK/6(1 − α). And the resulting inflation is eternal.
The Nambu-Goldstone theorem applies with the dynamical spontaneous scale symmetry breaking by nonzero $K$, and there is a dilaton. We will mention some of the properties of the dilaton, with a more detailed discussion in [14]. If the underlying Weyl scale symmetry is maintained throughout the full theory (including quantum corrections), then the massless dilaton has at most derivative coupling to matter and the Brans-Dicke constraints go away.

We discuss in Section III a model with two scalars, $\phi$ and $\chi$. The generalization of the Weyl current is straightforward. After the initial expansionary phase establishing constant $K$, the fields readily generate a period of slow-roll inflation as their VEV’s migrate along an ellipse defined by constant $K$. If the potential $V(\phi)$ is scale invariant and has a nontrivial minimum with non-vanishing VEV’s, it follows that $V(\phi)$ vanishes at its minimum and that it has a flat direction corresponding to a definite ratio of the scalar field VEV’s. The slow-roll inflationary period is terminated by a period of “reheating” in which the fields acquire large kinetic energy which is rapidly damped by expansion. Subsequently the fields flow toward an infrared (IR) fixed point that determines the ratio of their VEV’s in terms of the couplings appearing in the scalar potential (this was studied in a two field example in ref.[12]). The fixed point is the intersection of the potential flat direction with the ellipsoid. If the potential does not have a non-trivial minimum, gravitational effects prevent the roll to the scale invariant minimum and the inflation is eternal, i.e., there is then a relic cosmological constant.

In Section IV we discuss the $N$-scalar scheme and the analytic solution for the inflationary phase in the two scalar scheme. We consider generalized inflationary fixed point of the $N$ scalar schemes, and the $N=3$ model is examined in detail.

If scale symmetry is broken through quantum loops, the resulting trace anomaly implies that $K_\mu$ is no longer conserved. Then the field VEV’s, hence $K$, would relax to zero, and with it would go the Planck mass. To avoid this it is necessary to maintain the Weyl symmetry throughout. One of our main theses is that this is possible, i.e., the Weyl symmetry can be maintained at the quantum level if no external mass scales are introduced into the theory during the process of renormalization.

In Section V we turn to the quantum effects. We first describe how the Einstein and Klein-Gordon equations are conventionally modified by scale anomalies, leading to the modified field $K_\mu$ current and the kernel $K$. Our main goal here is to describe and construct effective Coleman-Weinberg-Jackiw [15, 16] actions where the couplings run with fields.

In Weyl invariant theories there can be no absolute meaning to mass; only Weyl invariant dimensionless ratios of mass scales will occur. It is therefore crucial that no “external mass scales” are introduced at the quantum level in renormalizing the theory. This implies that counterterms must be field dependent and are ultimately specified by the overall constraint that the renormalized action remains Weyl invariant. In the effective action the running couplings must therefore depend exclusively upon Weyl invariant ratios of values of field VEV’s, e.g., $\lambda(\phi_c/\chi_c)$, rather than ratios involving some external mass scale, e.g., $\lambda(\phi_c/M)$. This approach makes no specific reference to any particular regularization method (see [17, 18]). The renormalization group with nontrivial $\beta$-functions remains, however the running of parameters, is now given in terms of Weyl invariants.

We give general formal arguments in Section V and more details will be given elsewhere [19]. In Section V we explore a simple two scalar model of quantum effects with a particular choice of the running renormalized couplings which are expected to emerge in detailed calculations. Since the renormalization group running occurs in Weyl invariants such as $\phi_c/\chi_c$, rather than $\phi_c/M$, we find that the ellipse can be significantly distorted by these effects. $K$ becomes constant, and a non-trivial ratio of VEV’s $\phi_c/\chi_c$ develops which is suggestive that a hierarchical relationship between $M_P, M_{GUT}$ and $m_{Higgs}$ might emerge from this dynamics in more detailed models. We follow with conclusions.

II. SINGLE NON-MINIMAL SCALAR

A. The Action

We begin by establishing some notation. A standard Einstein gravitation in our sign conventions with a minimally coupled massless scalar field, $\sigma$, and metric tensor $g$ and cosmological constant, $\Lambda$, is an action of the form:

$$ S = \int \sqrt{-g} \left( \frac{1}{2} g^{\mu\nu} \partial_\mu \sigma \partial_\nu \sigma - \Lambda + \frac{1}{2} M_P^2 R \right) $$

where the Einstein-Hilbert term contains the scalar curvature, $R$, and the Planck mass: $M_P^2 = (8\pi G)^{-1}$. For small $\sigma$ this action describes a deSitter universe with Hubble parameter:

$$ H^2 = \frac{\Lambda}{3M_P^2} \tag{3} $$

Presently, we consider a theory of a real scalar field, $\phi$, in which the Einstein-Hilbert term has been replaced with the non-minimal scalar coupling $-(1/2)\alpha \phi^2 R$, and we choose a scale invariant potential $V(\phi) = \lambda \phi^4/4$:

$$ S = \int \sqrt{-g} \left( \frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - \frac{\lambda}{4} \phi^4 - \frac{1}{12} \alpha \phi^2 R \right) \tag{4} $$

Assuming $\phi$ acquires a VEV, we would generate a Planck mass from eq.(4) of the form $M_P^2 = -\alpha \phi^2/6$. We thus require $\alpha < 0$, to obtain the correct sign for the Einstein-Hilbert term, as in eq.(2).

The theory of eq.(4) is globally scale invariant. The invariant scale transformation corresponds to the global limit of the “Weyl transformation”:

$$ g_{\mu\nu} \to e^{-2\epsilon(x)} g_{\mu\nu} \quad \phi \to e^{\epsilon(x)} \phi(x) \tag{5} $$

---

1. Our metric signature convention is $(1, -1, -1, -1)$, and our sign convention for the Riemann tensor is that of Weinberg [20]; our conventions are identical to those of reference [21].
with $\varepsilon(x) = \varepsilon$ being constant in space-time. If we perform an infinitesimal local transformation as in eq.(5) on the action, we obtain the Noether current:

$$K_\mu = \frac{\delta S}{\delta \partial_\mu \varepsilon} = (1 - \alpha) \phi \partial_\mu \phi.$$  

Equation (6) is the conservation equation of the Noether current, which is a consequence of the invariance of the action under infinitesimal local transformations. If we substitute $\alpha = 0$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 1$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

For $\alpha = 1$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 0$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

Starting with an arbitrary classical field $\phi$, after a period of general expansion, in some regions of space $\phi$ becomes approximately spatially constant, but time dependent. The conservation law of eq.(12) becomes:

$$K + 3H \dot{K} = 0$$  

Equation (14) is the conservation equation of the Noether current, which is a consequence of the invariance of the action under infinitesimal local transformations. If we substitute $\alpha = 0$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 1$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

If we take $\phi$ to be a function of time $t$ only, we have by eq.(14)

$$K(t) = c_1 + c_2 \int_0^t \frac{dt'}{a^3(t')}.$$  

Equation (15) is the conservation equation of the Noether current, which is a consequence of the invariance of the action under infinitesimal local transformations. If we substitute $\alpha = 0$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 1$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

Thus, with $\alpha < 0$ we have a self-consistent, exponential relaxation to constant $\phi = \phi_0 = \sqrt{2K/(1-\alpha)}$, and eternal inflation.

Note that this situation contrasts what happens in conventional Einstein gravity with a fixed $M_P$ and a $\lambda \phi^4/4$ potential. Inflation is possible for super Plankian values of $\phi$ which slow-roll to $\phi = 0$. Hence, while normal Einstein gravity causes $\phi$ to relax to zero, the scale-invariant gravity theory leads to constant nonzero $\phi = \phi_0$ which generates $M_P$ and eternal inflation.

Anticipating our discussion in Section V, we can ask how the trace anomaly, arising through quantum effects, would affect these conclusions? The Weyl current is not conserved if there are trace anomalies, and eq.(11) becomes:

$$D^\mu K_\mu = 4V(\phi) - \phi \frac{\partial}{\partial \phi} V(\phi)$$  

Equation (11) is the conservation equation of the Noether current, which is a consequence of the invariance of the action under infinitesimal local transformations. If we substitute $\alpha = 0$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 1$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

The term $D^\mu K_\mu$ is then zero, as discussed in section V. This maintains the vanishing of the $\text{rhs}$ of eq.(12), and the Planck mass is then stabilized.

2 There is also an anomaly associated with the running of $\alpha$. 

B. The Kernel

It is clear that the scale current can be written as $K_\mu = \partial_\mu K$ where the kernel $K = (1 - \alpha)\phi^2/2$. This has immediate implications for the dynamics of this theory. Consider a Friedman-Robertson-Walker (FRW) metric:

$$g_{\mu\nu} = \begin{bmatrix} 1, & -a^2(t), & -a^2(t) \end{bmatrix}, \quad H = \frac{\dot{a}}{a}$$  

$$G_{00} = -3\frac{a^2}{a^2}, \quad R = 6 \left( \frac{\dot{a}}{a} + \frac{\dot{a}^2}{a^2} \right)$$  

Equation (13) is the conservation equation of the Noether current, which is a consequence of the invariance of the action under infinitesimal local transformations. If we substitute $\alpha = 0$, we obtain the energy-momentum tensor of the field $\phi$. For $\alpha = 1$, we obtain the familiar equation of motion of the field $\phi$. Hence, we see that the Noether current is proportional to the energy-momentum tensor of the field $\phi$. If we take $\alpha > 0$, we obtain a source term proportional to the energy-momentum tensor of the field $\phi$. This means that the Noether current is a source of the field $\phi$.

C. Weyl Transformation and the Dilaton

We can identify the spatially constant field $\phi$ with a new field, $\sigma/f$ where $f$ is a “decay constant” (analog of $f_\pi$), and $\phi_0$ is constant:

$$\phi = \phi_0 \exp(\sigma/f),$$  \hspace{0.5cm} (18)

and perform the metric transformation:

$$g_{\mu\nu} = \exp(-2\sigma/f)\tilde{g}_{\mu\nu}$$  \hspace{0.5cm} (19)

Using $g_{\mu\nu} = \exp(-2\epsilon)\tilde{g}_{\mu\nu}$:

$$R \rightarrow \exp(2\epsilon)\tilde{R} + 6\exp(2\epsilon) \left( \partial^\mu \epsilon \partial_\mu \epsilon - \tilde{D}^\mu \partial_\mu \epsilon \right)$$  \hspace{0.5cm} (20)

where $\tilde{R}$, $(\tilde{D}^\mu)$ is the curvature (covariant derivative) expressed in terms of $\tilde{g}_{\mu\nu}$, we then have:

$$S = \int \sqrt{-g} \left[ \phi_0^2 \left( \frac{1}{2f^2} \tilde{g}^{\mu\nu} \partial_\mu \sigma \partial_\nu \sigma - \frac{\lambda}{4} \phi_0^4 \right) - \frac{1}{2} \alpha \phi_0^2 \left( \frac{1}{6} \tilde{R} + \frac{1}{f^2} \tilde{D}^\mu \partial_\mu \sigma \right) - \frac{1}{2} \tilde{D}^\mu \partial_\mu \sigma \right]$$  \hspace{0.5cm} (21)

The canonical normalization of the $\sigma$ field thus requires the decay constant $f = \sqrt{2K_0}$ where $K_0 = (1-\alpha)\phi_0^2/2$. Dropping a total divergence, and defining:

$$\Lambda = \frac{\lambda}{4}\phi_0^4; \hspace{0.5cm} M_P^2 = -\frac{1}{6} \alpha \phi_0^2$$  \hspace{0.5cm} (22)

we have:

$$S = \int \sqrt{-g} \left( \frac{1}{2} \tilde{g}^{\mu\nu} \partial_\mu \sigma \partial_\nu \sigma - \Lambda - \frac{1}{2} M_P^2 \tilde{R} \right)$$  \hspace{0.5cm} (23)

Therefore, we see that the scale invariant theory, eq.(4), can be viewed as the “Jordan frame,” equivalent to the “Einstein frame” action eq.(23), as we originally wrote down in eq.(2). The massless field $\sigma$ is the dilaton, but this feature is virtually hidden in the Einstein frame, since there $\sigma$ couples to gravity only through it’s stress tensor. Note the identical correspondence of eq.(16) with eq.(3).

Remarkably eq.(3) contains a hidden Weyl symmetry. We see that $\Lambda$ and $M_P^2$ are related to the $\phi_0^2$, and can be written in terms of the dilaton decay constant as:

$$\Lambda = \frac{\lambda}{4(1-\alpha)} f^4; \hspace{0.5cm} M_P^2 = -\frac{1}{6(1-\alpha)} \alpha f^2$$  \hspace{0.5cm} (24)

These relations are the analogue, in a chiral Lagrangian, of the Goldberger-Treiman relation, of the nucleon, $m_N$, to $f_\pi$ and the strong coupling constant $g_{NN\pi}$. The variation of the action of eq.(23) with respect to $\sigma/f$ yields the current, $K_\mu = f \partial_\mu \sigma$ which is the representation $K_\mu$ in the Einstein frame, and the analogue of the axial current, $f_\pi \partial_\mu \pi$, of the pion.

The dilaton reflects the fact that the exact scale symmetry remains, though hidden in the Einstein frame. We can rescale both the VEV $\phi_0 \rightarrow e^\epsilon \phi_0$ and the Hubble constant $H_0 \rightarrow e^\epsilon H_0$ while their ratio remains fixed:

$$\frac{H_0^2}{\phi_0^4} = \frac{\lambda}{2|\alpha|}$$  \hspace{0.5cm} (25)

It is straightforward to extend this effective Lagrangian to matter fields. If the dilaton develops a “hard coupling” to, e.g., the nucleon, then stars would develop dilatonic halo fields. This would then be subject to strict limits from Brans-Dicke theories, and the models would fail to give acceptable inflation. However, if all ordinary matter fields have masses that are ultimately associated with the spontaneous breaking of the Weyl scale symmetry, then the dilaton only couples derivatively. There are then no Brans-Dicke-like constraints, as no star or black-hole, etc., will generate a $\sigma$ field halo. In a subsequent paper [19] we will discuss the dilaton phenomenology in greater detail.

III. TWO SCALAR THEORY

A. Classical Two Scalar Action

Consider an $N = 2$ model, with scalars $(\phi, \chi)$, and the potential:

$$W(\phi, \chi) = \frac{\lambda}{4} \phi^4 + \frac{\xi}{4} \chi^4 + \frac{\delta}{2} \phi^2 \chi^2$$  \hspace{0.5cm} (26)

The action takes the form:

$$S = \int \sqrt{-g} \left( \frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi + \frac{1}{2} g^{\mu\nu} \partial_\mu \chi \partial_\nu \chi ight)$$  \hspace{0.5cm} (27)

This has been studied in [1–4, 12]. For example, [2] study this theory in the context of a unimodular gravity and perform a Weyl transformation taking eq.(27) from a Jordan frame to an Einstein frame. We follow the approach of [12] and work directly in the defining frame of eq.(27), and then just follow the dynamics. The result is an effective, emergent Einstein gravity where the Planck mass is induced by the VEV’s of $\phi$ and $\chi$. We will see in Section IV that, due to the conserved $K$-current, the slow-roll inflation of the classical system is amenable to an analytic treatment. We will also extend this to include quantum corrections that have a significant effect in the next section.

The sequence of steps follows those of the previous single scalar case. The Einstein equation is:

$$M_P G_{\alpha\beta} = \left( \left( 1 - \frac{1}{3} \alpha_1 \right) \partial_\alpha \phi \partial_\beta \phi + \left( 1 - \frac{1}{3} \alpha_2 \right) \partial_\alpha \chi \partial_\beta \chi ight) - g_{\alpha\beta} \left( \partial^\mu \partial_\mu \phi - g_{\alpha\beta} \left( \frac{1}{2} - \frac{1}{3} \alpha_1 \right) \partial_\alpha \chi \partial_\beta \chi \right. + \left. \frac{1}{3} \alpha_1 \left( \partial_\alpha \phi \partial_\beta \phi - \partial_\alpha \chi \partial_\beta \chi \right) + \frac{1}{3} \alpha_2 \left( \partial_\alpha \phi \partial_\beta \phi - \partial_\alpha \chi \partial_\beta \chi \right) \right)$$  \hspace{0.5cm} (28)
where:
\[ M^2_P = -\frac{1}{\xi} (\alpha_1 \phi^2 + \alpha_2 \chi^2) \]  

(29)

The trace of the Einstein equation becomes:
\[ R = \frac{1}{M^2_P} \left( (\alpha_1 - 1) \partial^\mu \phi \partial_\mu \phi + (\alpha_2 - 1) \partial^\mu \chi \partial_\mu \chi \right. \\
+ \alpha_1 \phi D^2 \phi + \alpha_2 \chi D^2 \chi + 4W(\phi, \chi) \)  

(30)

The Klein-Gordon equations for the scalars are:
\[ 0 = D^2 \phi + \delta \phi \chi^2 + \frac{1}{6} \alpha_1 \phi R \\
0 = D^2 \chi + \delta \phi \chi^2 + \frac{1}{6} \alpha_2 \chi R \]  

(31)

and we again use the trace equation to eliminate \( R \):
\[ 0 = \phi D^2 \phi - \frac{\alpha_1 \phi^2}{6M^2_P} \left( (1 - \alpha_1) \partial^\mu \phi \partial_\mu \phi + (1 - \alpha_2) \partial^\mu \chi \partial_\mu \chi \right. \\
- \alpha_1 \phi D^2 \phi - \alpha_2 \chi D^2 \chi - 4W \left) + \delta \phi \chi^2 + \lambda \phi^4 \right. \\
0 = \chi D^2 \chi - \frac{\alpha_2 \chi^2}{6M^2_P} \left( (1 - \alpha_1) \partial^\mu \phi \partial_\mu \phi + (1 - \alpha_2) \partial^\mu \chi \partial_\mu \chi \right. \\
- \alpha_1 \phi D^2 \phi - \alpha_2 \chi D^2 \chi - 4W \left) + \delta \phi \chi^2 + \xi \chi^4 \right. \]  

(32)

We again see that the sum of the Klein-Gordon equations implies the conserved current, where the potential terms cancel owing to scale invariance:
\[ 0 = D_\mu [ (1 - \alpha_1) \partial^\mu \phi + (1 - \alpha_2) \chi \partial^\mu \chi ] \]  

(33)

so:
\[ K_\mu = (1 - \alpha_1) \phi \partial^\mu \phi + (1 - \alpha_2) \chi \partial^\mu \chi \]  

(34)

is conserved \( D_\mu K_\mu = 0 \). The kernel is now given by:
\[ K = \frac{1}{2} \left[ (1 - \alpha_1) \phi^2 + (1 - \alpha_2) \chi^2 \right] \]  

(35)

B. Synopsis of Two Scalar Dynamics

The two scalar theory has a number of interesting features, which we will summarize presently. We first discuss the classical case and, after the discussion of the scale invariant renormalization procedure, we consider the modifications that can occur when including radiative corrections in Section V.

The potential of eq.(26) has the general form:
\[ W(\phi, \chi) = \frac{\xi}{4} (\chi^2 - \xi \phi^2)^2 + \frac{\lambda'}{4} \phi^4 \]  

(36)

with \( \lambda' = \lambda - \xi \phi^4 \). For the case \( \lambda' = 0 \) the potential has a flat direction with \( \chi = \phi \), and the vacuum energy vanishes for non-zero VEV’s of the fields.

The theory can lead to a realistic cosmological evolution as illustrated in Fig.(1) for a representative choice of parameters and initial conditions. In an initial “transient phase,” the theory will redshift from arbitrary initial field values and velocities, \( (\phi_0, \chi_0) \). Owing to the conserved \( K \) current, the redshifting will cause \( \chi(t) \to 0 \) and the \( K_0 \) charge density to dilute away as \( \sim a(t)^{-3} \) leading to a state with constant kernel \( K \). The arbitrary, nonzero value of \( K \), determines the scale of the Planck mass, \( K \sim M^2_P \), and spontaneously breaks scale symmetry. The fields \( (\phi, \chi) \) are now approximately constant in space VEV’s and are constrained to lie on the ellipse defined by eq.(35). This initial location of the VEV’s on the ellipse, \( (\phi(0), \chi(0)) \), is random.

As \( K \) settles down to its constant value, Einstein gravity has emerged with a fixed Planck mass. This can be seen analytically for the classical case as in Section III.C below. The initial values of \( (\phi_0, \chi_0) \) are random and would not be expected to lie on the flat direction.

For a significant region of initial values the fields then slow-roll along the ellipse, migrating toward a minimum of the potential and generating a period of inflation. The flat direction is a ray in the \( (\phi, \chi) \) plane that intersects the ellipse defined by the kernel, eq.(35). If we assume \( \zeta < 1 \) this intersection occurs near the right-most end of the ellipse where \( \xi = \phi \) in quadrant I \( (\phi, \chi) > 0 \) in Fig.2. Note that \( \zeta < 1 \) is a particular choice of the dynamics, since for \( \zeta < 1 \) the flat direction can be arbitrary in the \( (\phi, \chi) \) plane, and the inflation can still be significant, but we will not then generate a large hierarchy in the VEV’s of \( \phi \) and \( \chi \).

The inflationary period ends when the slow-roll conditions are violated and the system enters a period of “reheating.”
when the potential energy is converted to kinetic energy which rapidly redshifts. Although this period cannot be solved analytically a numerical simulation shows that the kernel remains constant and that the fields ultimately resume slow-roll with expectation values that are in the domain of attraction of an infra red fixed point [12]. The fixed point is determined by the parameters of the potential and the \( \alpha_i \) and, if the potential has a non-trivial minimum corresponding to \( \lambda^I = 0 \) in eq(36), the fixed point corresponds to the minimum of the potential with vanishing cosmological constant (otherwise the fixed point corresponds to non-vanishing VEV’s, with non-vanishing potential energy, leading to eternal inflation).

C. Inflation in the Two Scalar Scheme

In this section we give a detailed analysis of the inflationary era in the two scalar theory and determine the full analytic solution in the slow-roll regime.

In what follows we will be interested in a large hierarchy between the scalar VEV’s that can develop after an initial period of inflation. In this case the large field VEV (we will choose parameters such that this is the \( \phi \) VEV) sets the magnitude of the Planck scale while the small field VEV sets the scale in the “matter” sector characterised by the \( \chi \) field.

As before we assume the potential of eq.(26), and that there is an Hubble size volume in which the fields are time dependent but spatially constant. Then following the argument in Section II B we see that the kernel \( K \) becomes a constant, which we take to be an arbitrary mass scale (related ultimately to the Planck mass \( K \sim M_P^2 \)). The residual motion of the scalars during slow-roll is constrained to lie on the \( K \) = constant ellipse and is then described by a difference of the KG equations. We thus form the convenient combination:

\[
\frac{D^2 \phi}{\phi} - \frac{D^2 \chi}{\chi} = -(\alpha_2 \lambda - \alpha_1 \delta) \phi^2 + (\alpha_1 \xi - \alpha_2 \delta) \chi^2
\]

We take the slow-roll limit of eq.(37) and we pass to the “inflation derivative” \( D^2 \phi \to 3H \phi = 3H^2 \partial_N \phi \) where \( N = \ln(a(t)) \) hence \( \partial \phi = H \partial_N \phi \):

\[
\frac{3}{2} H^2 \left( \alpha_2 \frac{\partial_N \phi^2}{\phi} - \alpha_1 \frac{\partial_N \chi^2}{\chi} \right) = -(\alpha_2 \lambda - \alpha_1 \delta) \phi^2 + (\alpha_1 \xi - \alpha_2 \delta) \chi^2
\]

We eliminate \( H^2 \) using the (00) Einstein equation in the slow-roll limit:

\[
M_P^2 G_{00} = -\frac{1}{2} H^2 (\alpha_1 \phi^2 + \alpha_2 \chi^2) \approx g_{00} W
\]

Without loss of generality we can choose the ellipse \( K = 1 \) and we can map quadrant I of the ellipse into the variables:

\[
x = (1 - \alpha_1) \phi^2 \quad \text{and} \quad y = (1 - \alpha_2) \chi^2 \quad (40)
\]

The ellipse then becomes the line segment \( 1 = x + y \) in quadrant I. With the fields constrained to be on the ellipse, we see that \( (x,y) \) are each constrained to range from 0 to 1.

The slow-roll differential equation on the ellipse, eq.(38), can then be written as:

\[
\partial_N x = \frac{S(x)}{W(x)} x (1 - x) (x - x_0).
\]

where:

\[
S(x) = \frac{2}{3} \frac{((1 - \alpha_2) A + (1 - \alpha_1) B)}{(1 - \alpha_2)^2 (1 - \alpha_1)^2 (1 - \alpha_1)} \times \frac{((1 - \alpha_2) x + \alpha_2 (1 - \alpha_1))}{(\alpha_2 (1 - x) + \alpha_1 x)}
\]

\[
A = (\alpha_2 \lambda - \alpha_1 \delta)
\]

\[
B = (\alpha_1 \xi - \alpha_2 \delta)
\]

and:

\[
W(x) = \frac{\lambda x^2}{4(1 - \alpha_1)^2} + \frac{\xi (1 - x)^2}{4(1 - \alpha_2)^2} + \frac{\delta x (1 - x)}{2(1 - \alpha_1)(1 - \alpha_2)}
\]

3 By coupling \( \chi \) to standard model fields one has that energy will be transferred - the Universe will “reheat” - during the oscillatory phase; the oscillations will be damped driving the dynamics to the fixed point (which remains unchanged)

4 In [28, 29] this field models the Higgs of the Standard Model.
\(x_0\) is the “fixed point” in \(x\), as defined in [12], and takes the form:

\[
x_0 = \frac{B(1 - \alpha_1)}{A(1 - \alpha_2) + B(1 - \alpha_1)} \tag{45}
\]

The solutions to eq.(41) depend critically on the behaviour of \(S(x)/W(x)\). To demonstrate there is a region of parameter space that does undergo slow-roll inflation we consider the case studied in ref.[12], in which \(\xi, \delta \gg \lambda\), such that \(B > A\), \(x_0 \approx 1\) and, during the initial inflationary era, \(W \approx \xi(1 - x)^2/4(1 - \alpha_2)^2\). In this case:

\[
\partial N x = -\frac{4}{3} \frac{\alpha_1}{(1 - \alpha_1)} \frac{(\alpha_2 - \alpha_1 x + \alpha_2 (1 - \alpha_1))}{(\alpha_2 + (\alpha_1 - \alpha_2)x)} \tag{46}
\]

The above result is an exact solution for slow-roll in the model of [12]. The slow-roll conditions are readily satisfied for small, negative \(\alpha_1\) in which case:

\[
\partial N x \approx -\frac{4}{3} \frac{\alpha_1}{(1 - \alpha_1)} x\tag{47}
\]

and \(x(t)\) will roll from an initial \(x(0)\) toward \(x(t_\infty) = x_0 \approx 1\) where \(t_\infty\) is the time at the end of inflation.

Eq.(46) can readily be integrated:

\[
\ln \frac{x(t)}{x(0)} - \alpha_1 \ln \left(\frac{\alpha_2 - \alpha_1 x(t) - \alpha_2 (1 - x(t))}{\alpha_2 - \alpha_1 x(0) - \alpha_2 (1 - x(0))}\right) = -\frac{4}{3} \alpha_1 \ln \left(N(t) - N(0)\right) \tag{48}
\]

In this limit of small \(\alpha_1\), eq.(48) implies the number of e-folds of inflation, \(N\), is given by

\[
N = N(t_\infty) - N(0) = \frac{3}{4 \alpha_1} \ln \left(\frac{x(0)}{x(t_\infty)}\right) \tag{49}
\]

Inflation ends when slow-roll ceases corresponding to the inflation parameter, \(\epsilon\), approaching unity: \(\epsilon = -(1/2) (d \ln H^2/dN) \approx 1\). This implies:

\[
\frac{2}{3} \left(1 - x(t_\infty)\right) - \frac{\alpha_1}{1 - x(t_\infty) + \alpha_1/\alpha_2} \approx 1 \tag{50}
\]

hence, when \(x(t_\infty) = 1 - O(\alpha_1)\). The number of e-folds of inflation is weakly governed by the initial value on the ellipse, \(x(0)\). This is any value of order, but less than, unity, e.g., \(x(0) \sim 0.5\), so to get large \((N(t_\infty) - N(0))\) we require \(|\alpha_1| \ll 1\).

The resulting values for the spectral index, \(n_s\), and the tensor to scalar fluctuation ratio, \(r\), are presented in [12]. An acceptable value for \(n_s\) is possible for \(|\alpha_1| < 0.1\). The value of \(r\) is sensitive to \(\alpha_2\) and is between one and two orders of magnitude less than the current observational bound for \(|\alpha_2| > 1\).

D. The “reheat” phase

Once \(\epsilon \approx 1\), the slow-roll conditions are violated and there is a period of rapid field oscillation - the “reheat” phase in which the scalar fields acquire large kinetic energy. We have not been able to find an analytic solution in this phase but a numerical study confirms this is the case.

An example is shown in Fig.(1) where it may be seen that after about 150 e-folds of inflation the Hubble parameter drops very rapidly before rolling to the infra-red fixed point value. As the Hubble parameter drops the fields undergo very rapid oscillations (too rapid to show up in the Figure) after which they re-enter the slow-roll regime with values in the domain of attraction of the IR stable fixed point. During the “reheat” phase, and all subsequent evolution, the kernel, \(K\), remains constant.

E. Infrared fixed point

After the “reheat” phase the fields enter a second slow-roll phase that is again described by eq(41). One may see that this equation has an IR stable fixed point given by

\[
x(t \to \infty) = x_0 \tag{51}
\]

This corresponds to the final ratio of the field VEV’s given by

\[
\frac{\langle \chi_f \rangle^2}{\langle \phi_f \rangle^2} = \frac{\alpha_2 \lambda - \alpha_1 \delta}{\alpha_1 \xi - \alpha_2 \delta} \tag{52}
\]

A large hierarchy between the “matter” sector scale and the Planck scale requires that the \(\chi\) mass be hierarchically small compared to the Planck scale and this in turn requires \(\delta \ll \langle \chi_f \rangle^2 / \langle \phi_f \rangle^2\). In addition it is desirable that the cosmological constant after inflation be small or zero and this in turn requires a fine tuning of the parameters in the potential so that it is (or is close to) a perfect square. For this to happen we need \(\lambda \approx \langle \chi_f \rangle^4 / \langle \phi_f \rangle^4\). Note that these choices are consistent with our assumption that \(W \sim \xi \chi^4\) and \(B \gg A\) during inflation when \(\phi\) and \(\chi\) are both large.

What happens to the scale factor in the IR? For static scalar fields the FRW equation is

\[
3 M^2 \left(\frac{d a}{d t}\right)^2 = W = \left(\frac{\lambda}{4} + \frac{\xi \mu^4}{4} + \frac{\delta \mu^2}{2}\right) \phi_0^4 \tag{53}
\]

(while \(\mu^2 \equiv \langle \chi_f \rangle^2 / \langle \phi_f \rangle^2\)) and we can define an effective cosmological constant \(\Lambda_{\text{eff}} = \left(\lambda/4 + \xi \mu^4/4 + \delta \mu^2/2\right)\phi_0^4 / (\alpha_1 + \alpha_2 \mu^2)\). With the ordering of the couplings discussed above \(\Lambda_{\text{eff}} \ll \xi \chi_0^4 / 4 M^2\). If this is non-zero there will be a late stage of eternal inflation. To obtain zero cosmological constant requires fine tuning of the couplings corresponding to the potential having the form of a perfect square.

F. The Dilaton

The dilaton effective action can be derived in analogy to the single scalar case in Section II C (see IV. B below). Once the ratio of fields is fixed, the dilaton can readily be identified in the two scalar case from the fact that the scale current has the
form $K_{\mu} \propto \partial_{\mu} \sigma$ and under a scale transformation $\sigma \rightarrow \sigma + \epsilon$. Since the scale current has the form $K_{\mu} = \partial_{\mu} K$ with $K$ given by eq.(35) we know that $\sigma$ must be some function of $K$. In order for scale symmetry to act as a shift symmetry implying

$$K = \frac{1}{2} f^2 e^{2\sigma/f}$$  \hspace{1cm} (54)

with

$$f = \sqrt{2\kappa_0} = \sqrt{(1 - \alpha_1)\phi_0^2 + (1 - \alpha_2)\chi_0^2}$$  \hspace{1cm} (55)

Upon passing to the “Einstein frame,” the dilaton $\sigma$ appears in the action only in its kinetic term as for the single scalar case, eq.(23). The dilaton decoupling is due to the exact underlying global Weyl invariance that is broken only spontaneously via the VEV of $K$. This will be discussed in detail elsewhere [19].

IV. N-SCALAR CASE

The analysis generalizes readily to the case of $N$-scalars. Here the scale current and its associated kernel are derived and the dilaton identified. It is also shown that the IR fixed point structure determines the ratios of all the scalar field VEV’s in terms of the couplings entering the potential, so any hierarchical structure can emerge if the couplings are themselves hierarchical.

However, the existence of an initial inflationary era needs to be justified if there are large couplings between the fields as this can prevent a period of slow-roll from occurring. This is of particular relevance if we treat the additional scalars as a new field VEV’s in terms of the couplings entering the potential, so any hierarchical structure can emerge if the couplings are themselves hierarchical. To illustrate this we consider below the case of 3 scalar fields, $\phi_i$, with large self and cross couplings between the two “matter” fields.

A. N-SCALAR ACTION

The mathematical generalization to $N$-scalars is straightforward. Consider a set of $N$ scalar quantum fields $\phi_i$, $i = (1, 2, \ldots N)$ and action:

$$S = \int \sqrt{-g} \left( \sum_{i} \frac{1}{2} g^{\mu \nu} \partial_{\mu} \phi_i \partial_{\nu} \phi_i - W(\phi_i) - \sum_{i} \alpha_i \phi_i^2 \right) R$$  \hspace{1cm} (56)

The Einstein equation is:

$$\frac{1}{6} \sum_i \alpha_i \phi_i^2 G_{\alpha \beta} = g_{\alpha \beta} W(\phi_i)$$

$$+ \sum_i \left[ \left( 1 - \frac{\alpha_i}{3} \right) \partial_\mu \phi_i \partial_\nu \phi_i - \left( \frac{1}{3} - \frac{\alpha_i}{3} \right) g_{\alpha \beta} \partial_\mu \phi_i \partial_\nu \phi_i \right]$$

$$+ \left( \frac{\alpha_i}{3} \right) \left( g_{\alpha \beta} \phi_i D^2 \phi_i - \phi_i D_\alpha D_\beta \phi_i \right)$$  \hspace{1cm} (57)

The trace of the Einstein equation becomes:

$$- \frac{1}{6} \left( \sum_i \alpha_i \phi_i^2 \right) R = 4W(\phi_i)$$

$$+ \sum_i \left[ (\alpha_i - 1) \partial_\mu \phi_i \partial_\nu \phi_i + \alpha_i \phi_i D^2 \phi_i \right]$$  \hspace{1cm} (58)

The $N$ Klein-Gordon equations are:

$$0 = D^2 \phi_i + \frac{\delta}{\delta \phi_i} W(\phi_i) + \frac{1}{6} \alpha_i \phi_i R$$  \hspace{1cm} (59)

and we can write the sum of the Klein-Gordon equations:

$$- \frac{1}{6} \left( \sum_i \alpha_i \phi_i^2 \right) R = \sum_i \phi_i D^2 \phi_i + \phi_i \frac{\delta}{\delta \phi_i} W(\phi_i)$$  \hspace{1cm} (60)

Combine eqs.(58,60) to eliminate $R$:

$$0 = \sum_i \left[ (\alpha_i - 1) \partial_\mu \phi_i \partial_\nu \phi_i + (\alpha_i - 1) \phi_i D^2 \phi_i \right]$$

$$+ 4W(\phi_i) - \sum_i \phi_i \frac{\delta}{\delta \phi_i} W(\phi_i)$$  \hspace{1cm} (61)

If we assume a scale invariant potential we have:

$$0 = 4W(\phi) - \sum_i \phi_i \frac{\delta}{\delta \phi_i} W(\phi)$$  \hspace{1cm} (62)

We thus see that eqs.(61,62) implies a covariantly conserved current:

$$K_{\mu} = \sum_i (1 - \alpha_i) \left( \phi_i \partial_{\mu} \phi_i \right)$$  \hspace{1cm} (63)

where $D_\mu K^\mu = 0$. The current $K_{\mu}$ arises from a “Weyl gauge transformation” and the $K_\mu$ current has a “kernel,” i.e., it can be written as a gradient, $K_{\mu} = \partial_{\mu} K$ where:

$$K = \frac{1}{2} \sum_i \phi_i^2 (1 - \alpha_i)$$  \hspace{1cm} (64)

B. N-SCALAR DILATON

The scale symmetry is spontaneously broken by the constraint of eq.(63). The fixed value of $K$ has been generated inertially by the dynamical dilution of the birth of the charge density, $K_0$. The value of $K$ is arbitrary and it can be shifted at no cost in energy due to overall Weyl invariance. This implies a dilaton. We can define the dilaton as:

$$\sigma = \frac{f}{2} \log \left( \frac{2K}{f^2} \right)$$  \hspace{1cm} (65)

To obtain the dilaton action we perform a local Weyl transformation using the dilaton field itself:

$$g_{\mu \nu}(x) \rightarrow \exp(-2\sigma(x)/f)g_{\mu \nu}(x)$$

$$\phi_i(x) \rightarrow \exp(\sigma(x)/f)\phi_i(x)$$  \hspace{1cm} (66)
Hence, the action $S$ of eq.(56) becomes $S + \delta S$ with:

$$\delta S = \int \sqrt{-g} \left[ \frac{1}{f} \sum_i (1 - \alpha_i) \phi_i \partial_{\mu} \phi_i (\partial^\mu \sigma(x)) + \frac{1}{f^2} \sum_i (1 - \alpha_i) \phi_i^2 (\partial_\rho \sigma(x) \partial^\rho \sigma(x)) \right]$$

$$= \int \sqrt{-g} \left[ \frac{1}{f} K_\mu (\partial^\mu \sigma(x)) + \frac{K}{f^2} (\partial_\rho \sigma(x) \partial^\rho \sigma(x)) \right]$$

(67)

This implies

$$f = \sqrt{2K}$$

(68)

is the dilaton decay constant, (for constant $K$). We can integrate the first term by parts and use the covariant $K_\mu$ current divergence, $D_\mu K^\mu = 0$, leaving a decoupled dilaton in the Einstein frame. Technically, we should include a Lagrange multiplier to enforce the constraint of eq.(64) on the $\phi_i$.

C. Slow-roll

The evolution equations take the form:

$$\begin{bmatrix} 1 + \frac{\alpha_i^2 \phi_i^2}{6M^2} & \frac{\alpha_i \alpha_j \phi_i \phi_j}{6M^2} & \cdots & \frac{\alpha_i \alpha_N \phi_i \phi_N}{6M^2} \\ \frac{\alpha_i \alpha_j \phi_i \phi_j}{6M^2} & 1 + \frac{\alpha_j^2 \phi_j^2}{6M^2} & \cdots & \frac{\alpha_j \alpha_N \phi_j \phi_N}{6M^2} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\alpha_i \alpha_N \phi_i \phi_N}{6M^2} & \frac{\alpha_N \alpha_j \phi_N \phi_j}{6M^2} & \cdots & 1 + \frac{\alpha_N^2 \phi_N^2}{6M^2} \end{bmatrix} \begin{bmatrix} 3H \dot{\phi}_1 \\ 3H \dot{\phi}_2 \\ \vdots \\ 3H \dot{\phi}_N \end{bmatrix} = \begin{bmatrix} \frac{4\alpha_1 \phi_1}{6M^2} W + W_{\phi_1} \\ \frac{4\alpha_2 \phi_2}{6M^2} W + W_{\phi_2} \\ \vdots \\ \frac{4\alpha_N \phi_N}{6M^2} W + W_{\phi_N} \end{bmatrix}$$

(69)

As before we assume that $U = \lambda N \phi_N^4$ dominates. We then have:

$$\begin{bmatrix} \frac{4\alpha_1 \phi_1}{6M^2} W + W_{\phi_1} \\ \frac{4\alpha_2 \phi_2}{6M^2} W + W_{\phi_2} \\ \vdots \\ \frac{4\alpha_N \phi_N}{6M^2} W + W_{\phi_N} \end{bmatrix} = \frac{4U}{6M^2} \begin{bmatrix} \alpha_1 \phi_1 \\ \alpha_2 \phi_2 \\ \vdots \\ \sum_{j=1}^{N-1} \alpha_j \phi_j \end{bmatrix}$$

(70)

We can now solve this system to get:

$$\begin{bmatrix} \dot{\phi}_1 \\ \dot{\phi}_2 \\ \vdots \\ \dot{\phi}_N \end{bmatrix} = \frac{4U}{\sum_{i=1}^N \alpha_i (1 - \alpha_i) \phi_i^2} \begin{bmatrix} \alpha_1 (1 - \alpha_N) \phi_1 \\ \alpha_2 (1 - \alpha_N) \phi_2 \\ \vdots \\ \sum_{j=1}^{N-1} \alpha_j (1 - \alpha_N) \phi_j \end{bmatrix}$$

(71)

We now define $X_i = \alpha_i \phi_i^2$ to get:

$$-\frac{3}{2} H \begin{bmatrix} \dot{X}_1 \\ \dot{X}_2 \\ \vdots \\ \dot{X}_N \end{bmatrix} = \frac{4U}{\sum_{i=1}^N (1 - \alpha_i) X_i} \begin{bmatrix} -\alpha_1 (1 - \alpha_N) X_1 \\ -\alpha_2 (1 - \alpha_N) X_2 \\ \vdots \\ -\alpha_N \sum_{j=1}^{N-1} (1 - \alpha_j) X_j \end{bmatrix}$$

(72)

If we now change variables to $\ln a$ and use the FRW equation:

$$3H^2 = \frac{U}{M^2}$$

(73)

we get:

$$\begin{bmatrix} X'_1 \\ X'_2 \\ \vdots \\ X'_N \end{bmatrix} = \frac{4}{3} \sum_{i=1}^N X_i \begin{bmatrix} -\alpha_1 (1 - \alpha_N) X_1 \\ -\alpha_2 (1 - \alpha_N) X_2 \\ \vdots \\ -\alpha_N \sum_{j=1}^{N-1} (1 - \alpha_j) X_j \end{bmatrix}$$

(74)

If we now take the $X_N \gg X_i$ (with $i = 1, \ldots, N - 1$) we get:

$$\begin{bmatrix} X'_1 \\ X'_2 \\ \vdots \\ X'_N \end{bmatrix} = \frac{4}{3} \begin{bmatrix} -\alpha_1 X_1 \\ -\alpha_2 X_2 \\ \vdots \\ -\alpha_N \sum_{i=1}^{N-1} \frac{\alpha_0}{1 - \alpha_0} \sum_{j=1}^{N-1} (1 - \alpha_j) X_j \end{bmatrix}$$

(75)

We can solve with $v_i = -\frac{4}{3} \alpha_i$ and $\gamma_i = \frac{\alpha_i (1 - \alpha_i)}{\alpha_i (1 - \alpha_i)}$.

$$X_i = X_i^{(0)} e^{v_i \ln a} \quad i = 1, \ldots, N - 1$$

$$X_N = C + \sum_{i=1}^N \gamma_i X_i^{(0)} e^{v_i \ln a}$$

(76)

D. Fixed point structure

The fixed points are found solving the $N$ equations:

$$4\alpha_i \phi_i^2 W + W_{\phi_i} = 0$$

(77)

We can rewrite this:

$$4\alpha_i \phi_i \sum_{jk} \phi_j^2 W_{jk} \phi_k^2 - 4 \sum_{j} \alpha_j \phi_j^2 \sum_k \phi_{jk} \phi_k^2 = 0$$

(78)

We divide out $\alpha_i \phi_i$ and define a set of $N$ matrices (labelled by $i$):

$$\alpha_i^{(i)} W_{jk} = \frac{\alpha_i}{\alpha_i} W_{jk}$$

(79)

We then have that the $N$ quadratic forms satisfy:

$$\sum_{jk} \phi_j^2 \alpha_i^{(i)} \phi_k^2 = 0$$

(80)
If this is to be possible then we must have \( \text{Det}[\mathcal{A}] = 0 \). But this is trivially so. If we pick the \( i \)th line, it will have that its \( i \)th line will be:

\[
\mathcal{A}^{(i)}_{ik} = W_{ik} - \frac{\alpha_i}{\alpha_0} W_{ik} = 0
\]

which means that its rank is less than or equal than \( N - 1 \). If all the \( \alpha_i \) are different, and if we assume \( W_{ik} \) is non-singular, we have that the rank is \( N - 1 \) and the solution will be a line in \( \phi_i^2 \) space with one free parameter, the overall scale. Interestingly, if some of the \( \alpha_i \) are degenerate, then the subspace will have a higher dimensionality.

E. Slow-roll in a 3-scalar scheme

The fixed point structure proves to be important in the slow-roll regime for the case that more than one coupling is significant in the scalar potential during slow-roll. We illustrate this presently in a particular 3-scalar example. Consider the case that the significant couplings during slow roll involve only two “matter” fields, \( \phi_2 \) and \( \phi_3 \). In this case the potential is dominantly of the form \( W = U + Y + T \) where:

\[
U = a \phi_2^4, \quad T = b \phi_2^4, \quad V = c \phi_2^2 \phi_3^2.
\]

In writing the slow-roll equations it is convenient to define new fields:

\[
X = -\alpha_1 \phi_1^2, \quad Y = -\alpha_2 \phi_2^2, \quad Z = -\alpha_3 \phi_3^2.
\]

Here \( \phi_2 \) and \( \phi_3 \) are the “matter” fields and we allow \( a, b \) and \( c \) to be \( O(1) \). Then the evolution equations in the slow-roll region have the form:

\[
\begin{pmatrix}
X' \\
Y' \\
Z'
\end{pmatrix} = -\frac{4}{3} \begin{pmatrix}
\frac{X+Y+Z}{B_1 X + B_2 Y + B_3 Z} & \frac{1}{(U+V+T)} \\
\alpha_1 & 0 & 0 \\
\alpha_2 & 0 & 0 \\
\alpha_3 & 0 & 0
\end{pmatrix} \begin{pmatrix}
\beta_3 (U+V) + \beta_2 (T+V) \\
\beta_2 (U+V) + \beta_1 (T+V) \\
\beta_1 (U+V) + \beta_3 (T+V)
\end{pmatrix}
\]

At this fixed point the evolution equation becomes:

\[
\begin{pmatrix}
X' \\
Y' \\
Z'
\end{pmatrix} = -\frac{4}{3} \begin{pmatrix}
\frac{X+Y+Z}{B_1 X + B_2 Y + B_3 Z} & \frac{1}{(U+V+T)} \\
-\alpha_1 X & \beta_2 (U+V) + \beta_3 (T+V) \\
\alpha_2 & \beta_1 X (U+V) + \beta_3 Z (U+V) - Y (T+V) \\
\alpha_3 & \beta_1 X (T+V) + \beta_2 Y (T+V) - Z (U+V)
\end{pmatrix}
\]

As in the two scalar case all derivatives are proportional to \( X \). Since \( X' \) is proportional to \( \alpha_1 \), if \( \alpha_1 \) is small the slow-roll constraints can indeed be satisfied. Also the evolution of \( Y \) and \( Z \) is much faster than \( X \) in the \( \alpha_1 \ll \alpha_2, \alpha_3 \) regime, so the inflationary era in the three scalar case will be similar to that in the two scalar case.

V. QUANTUM EFFECTS AND THE \( K_\mu \) CURRENT

We now consider the quantum effects. We first give a formal derivation of the conventional anomalies of the \( K_\mu \) current, and show how this is realized in a Coleman-Weinberg-Jackiw effective action. We then discuss how Weyl invariance can be maintained in the renormalized theory. This implies that renormalized quantities satisfy renormalization group equations in which they run in Weyl invariant combinations of fields, such as the ratios of scalar fields. The trace anomaly is then absent and the \( K_\mu \) current is identically conserved.

A. Weyl Invariance and Effective Action

Scale symmetry of a theory is normally considered to be broken by quantum loops. However, this happens because at some stage in the renormalization procedure, we introduce explicit “external” mass scales into the theory by hand. These are mass scales that are not part of the defining action of the theory, and they lead to non-conservation of the scale current.

The renormalization procedure, however, can be made scale invariant if we specify these quantities, not by introducing external mass scales, but rather by using the VEV’s of scalar fields that spontaneously break the scale symmetry but are part of the action itself. In this case, all logarithmic corrections arising in loops will have as their arguments scale invariant ratios of the internal field VEV’s. At the formal level, which we develop presently, the choice of dependencies of renormalized quantities appears arbitrary. However, calculations can be performed in which this arbitrariness is removed, and we will discuss this elsewhere [19].

We can see the usual “external mass parameter” renormalization in the famous paper of Coleman and Weinberg [15]. Starting with the classical \( \lambda \phi^4/4 \) theory, in their eq.(3.7) to renormalize \( \lambda \) at one-loop level, they introduce a mass scale \( M \). Once one injects \( M \) into the theory, one has broken scale symmetry. The one-loop effective potential then takes the
form:

$$V(\phi) = \frac{\beta_\lambda}{4} \phi^4 \ln(\phi/M). \quad (87)$$

where $\beta_\lambda$ is the one-loop approximation, $(\theta(\mu))$, to the $\beta-$function, $\beta_\lambda = d\lambda(\mu)/d\ln \mu$.

The heart of our proposal is to replace $M$ by the VEV of another dynamical field, e.g., $\chi$, that is part of the action of our theory:

$$V = \frac{\beta_\lambda}{4} \phi^4 \ln(\phi/\chi). \quad (88)$$

We see that the Weyl symmetry, $\phi \to e^{\varepsilon} \phi$, $\chi \to e^{\varepsilon} \chi$, is now intact.

The manifestation of this can be seen in the trace of the improved stress tensor [21]. In a single scalar theory, the trace anomaly is the divergence of the scale current $S_\mu$ and, using eq.(87), is given by [31]:

$$\partial_\mu S^\mu = T^\mu_\mu = 4V(\phi) - \phi \frac{\partial}{\partial \phi} V(\phi) = -\frac{\beta_\lambda}{4} \phi^4 \quad (89)$$

We see, as usual, that the trace anomaly is directly associated with the $\beta-$function of the coupling constant $\lambda$, and it exists on the rhs of eq.(89) because we have introduced the explicit scale breaking into the theory by hand via $M$. On the other hand, with two scalars we have:

$$\partial_\mu S^\mu = T^\mu_\mu = 4V - \phi \frac{\partial}{\partial \phi} V - \chi \frac{\partial}{\partial \chi} V = 0 \quad (90)$$

and this is vanishing with eq.(88). In effect, the trace anomaly has been transferred onto the lhs of the divergence equation, and the overall scale current conservation is maintained. We will see that this applies to the Weyl current $K_\mu$ as well.

Of course, there’s nothing wrong with the Coleman-Weinberg procedure, if one is only treating the effective potential as a subsector of the larger theory. That is, we are simply deferring the question of what is the true origin of $M$ in the larger theory? If, however, scale symmetry is to be maintained as an exact invariance of the world, then $M$ must be replaced by an internal mass scale that is part of action, i.e., $M$ must then be the VEV a field appearing in the extended action, such as $\chi$. If $M$ is replaced by a dynamical field in our theory, we will still have renormalization group evolution, but the resulting physics can now depend only upon ratios of dynamical VEV’s, and the running of couplings is given in terms of these ratios.

In fact, this is something we do in practice. All mass scales we measure in the laboratory are referred to other mass scales. Even derived scales, such as $\Lambda_{QCD}$, can be viewed as arising from a specification of $\alpha_{QCD}$ at some higher energy scale, such as a grand-unification scale, or the Planck mass, $M_{Pl}$. With the boundary condition, specifying $\alpha_{QCD}(M_{Pl})$ then $\Lambda_{QCD}$ is computed from the solution to the renormalization group equation. We obtain $\Lambda_{QCD} = cM_{Pl}$, where $c$ is an exponentially small coefficient (at one loop $c \sim \exp(-2\pi/|b_0|a_{QCD}(M_{Pl}))$). The question is then whether the fundamental reference scale, usually taken to be $M_{Pl}$, is an external input scale (such as the string constant), or the dynamical VEV of a field, such as $\chi$? In the latter case, we can in principle maintain an overall Weyl symmetry, and derived mass scales, such as $\Lambda_{QCD}$ become Weyl covariant: $\chi \to e^{\varepsilon} \chi$, $\Lambda_{QCD} \to e^{\varepsilon/2} \Lambda_{QCD}$.

**B. Conventional Anomalies of the $K_\mu$ Current**

Let us first formulate the anomalies of the $K_\mu$ current in the conventional renormalization framework that introduces an external mass scale $M$, in a theory with fields $\phi$, $g_{\mu\nu}, \ldots$

The Weyl transformation is:

$$\phi \to e^{\varepsilon} \phi, \quad g_{\mu\nu} \to e^{-2\varepsilon} g_{\mu\nu}, \ldots \quad (91)$$

The contravariant metric must then transform as $, g^{\mu\nu} \to e^{2\varepsilon} g^{\mu\nu}$. Here, if $\varepsilon(x)$ is a function of spacetime the transformation is local; if $\varepsilon$ is a constant in spacetime the transformation is global.

It is useful to define a differential operator that acts upon fields:

$$\delta_W \phi = \phi \delta \varepsilon, \quad \delta_W g_{\mu\nu} = -2g_{\mu\nu} \delta \varepsilon. \quad (92)$$

$\delta_W$ acts distributively, and, $\delta_W g_{\mu\nu} = +2g_{\mu\nu} \delta \varepsilon$, $\delta_W (\phi^{-1}) = -\phi^{-1} \delta \varepsilon$, and $\delta_W (\ln \phi) = \phi^{-1} \delta \varepsilon(\phi) = \delta \varepsilon$. In general, a field $\Phi$ of “mass dimension $D$” transforms covariantly as $\Phi \to e^{D\varepsilon} \Phi$ or $\delta_W \Phi = D\delta \varepsilon \Phi$.

Any locally Weyl invariant functional of fields $Q(\phi, g_{\mu\nu}, \ldots)$ satisfies:

$$\delta_W Q = 0 \quad (93)$$

We typically seek an effective Coleman-Weinberg-Jackiw action as a functional of classical fields for the study of inflation and spontaneous scale generation.

For the single scalar field $\phi$, consider the effective action, constructed by adding source to the fields, performing a Legendre transformation to the classical background fields, and integrating out quantum fluctuations [15, 16]. The result for a single scalar field theory is a functional of local classical background fields $\phi(x)$ and $g_{\mu\nu}(x)$:

$$S = \int \sqrt{-g} \left( \frac{1}{2} \delta^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - \frac{\lambda(\phi, g)}{4} \phi^4 - \frac{\alpha(\phi, g)}{12} \phi^6 R \right) \quad (94)$$

It is important to maintain locality in the Lagrangian, since general covariance is a local symmetry, and therefore requires that effective coupling constants be local functions of the fields.

---

5 Technically, the improved stress tensor is defined only for $\alpha = 1$, and in the flat space limit, but its anomaly parallels that of the $K_\mu$ current; the $K_\mu$ current is the more relevant scale current for $\alpha \neq 1$ theories.
Computing $\delta_W S$ we obtain the difference between the Einstein trace equation and the Klein-Gordon equations that yields the conservation law for $K_\mu$. This calculation is simplified by noting the local Weyl invariants satisfy:

$$\delta_W \int \sqrt{-g} \left( \frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - \frac{1}{12} \phi^2 R \right) = 0$$

$$\delta_W \int \sqrt{-g} \phi^4 = 0 \quad (95)$$

Hence:

$$\delta_W S = - \int \sqrt{-g} \delta \epsilon (D^\mu K_\mu + \frac{1}{4} (\delta_W \lambda) \phi^4 + \frac{1}{12} (\delta_W \alpha) \phi^2 R)$$

$$= 0 \quad (96)$$

where we integrate terms with $\partial_\mu (\delta \epsilon)$, by parts and discard surface terms. $K_\mu$ is given by the usual expression, but now contains the field dependent $\alpha(\phi, g_{\alpha \beta})$:

$$K_\mu = \frac{1}{2} \partial_\mu (1 - \alpha(\phi, g_{\alpha \beta})) \phi^2 \quad (97)$$

Eq.(96) defines the anomaly of the current:

$$D^\mu K_\mu = - \frac{1}{4} (\delta_W \lambda) \phi^4 - \frac{1}{12} (\delta_W \alpha) \phi^2 R \quad (98)$$

Consider the theory in a limit where we ignore all but internal $\phi$ loops. If we renormalize the effective action, introducing an external mass scale, $M$, then the $\beta$-functions are:

$$\phi \frac{\partial \lambda}{\partial \phi} = \beta_\lambda \left( = \frac{9 \lambda^2}{8 \pi^2} \right)$$

$$\phi \frac{\partial \alpha}{\partial \phi} = \beta_\alpha = (\alpha - 1) \gamma_\alpha \quad (\gamma_\alpha = \frac{3 \lambda}{8 \pi^2}) \quad (99)$$

where in brackets we quote the 1-loop computed values that follow from the $\phi$ loops in this theory.

Renormalizing with an external mass scale $M$ implies the constraint:

$$0 = \phi \frac{\partial \lambda}{\partial \phi} + M \frac{\partial \lambda}{\partial M}; \quad 0 = \phi \frac{\partial \alpha}{\partial \phi} + M \frac{\partial \alpha}{\partial M} \quad (100)$$

The $\partial / \partial M$ terms in the above equations are not due to the loop calculations, but rather, are external conditions we impose upon the couplings. That is, eq.(100) defines the functional dependence of the counterterms in the theory upon the external mass parameter $M$.

Note that the RG equation for $\alpha$ is $\propto (\alpha - 1)$, which is why we introduce the factor $\gamma_\alpha$ into its $\beta$-function definition. We can write $\phi \partial \alpha / \partial \phi = \alpha' \gamma_\alpha$ where, $\alpha' = (\alpha - 1)$, and this leads, for approximately constant $\gamma_\alpha$, to the solution eq.(101) below. The solutions to the RG equations in the approximation of a fairly constant or small $\lambda$, i.e., small $\beta_\lambda$, are, where the constants $c$ and $\alpha_0$ define the RG trajectories of the running couplings, $\lambda$ and $\alpha$.

Eq.(98) with eq.(101) then implies the form of the $K_\mu$ anomalies:

$$D^\mu K_\mu = - \frac{1}{4} \beta_\lambda \phi^4 - \frac{1}{12} \beta_\alpha \phi^2 R \quad (102)$$

The non-conservation of the $K_\mu$ current arises because the external mass parameter, $M$, breaks the Weyl scale symmetry.

Armed with the solutions of eqs.(101) we then have the effective action, where Weyl symmetry is broken by the effect of $M$:

$$S = \int \sqrt{-g} \left( \frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - \frac{1}{4} \beta_\lambda \ln \left( \frac{c \phi}{M} \right) \phi^4 + \frac{1}{2} \beta_\alpha \left( \alpha_0 - 1 \right) \left( \frac{\phi}{M} \right)^{\gamma_\alpha} \phi^2 R \right) \quad (103)$$

We cannot have our program of a stable, dynamically generated Planck mass without maintaining the Weyl symmetry, and we must therefore eliminate the explicit $M$ dependence and, hence, the anomalies in the $K_\mu$ current.

C. Maintaining Exact Weyl Scale Symmetry in Renormalized Quantum Theory

1. The Single Scalar Theory

To preserve the Weyl invariance, we need to eliminate the anomaly, which requires replacing the constraint eq.(100) that introduces the external mass scale $M$. From eq.(98) we see that we can maintain the Weyl invariance of eq.(92) in the renormalized theory provided the running coupling constants are Weyl invariant:

$$\delta_W \lambda = 0; \quad \delta_W \alpha = 0 \quad (104)$$

Eqs.(104) are thus a new constraint that replaces eq.(100). Hence, together with eq.(99), imposing eq.(104) we see from eq.(96) that: $D^\mu K_\mu = 0$.

This is an almost obvious result: the coupling constants must be local functions of Weyl invariants in order to maintain the Weyl symmetry. However, just as the $\partial / \partial M$ terms in eq.(100) are not due to the loop calculations, and are really part of the UV completion of the theory, neither do the dependencies upon various compensating fields implicit in eq.(104) necessarily arise from the loops alone. These are external conditions that presumably come from the UV completion.

Logically, this procedure is analogous to having a theory in which we have a chiral anomaly that violates a given axial current which we may want to gauge. This is usually done explicitly by judicious choice of fermion representations in the theory. However, it can also be done by constructing a Wess-Zumino-Witten term that generates the anomaly through bosonic fields and can be used to cancel the fermionic chiral anomaly. For example, the Wess-Zumino-Witten term for the original Weinberg model of a single lepton pair ($\nu, e$),
can be written in terms of the $0^-$ and $1^-$ mesons of QCD, and the $W$, $Z$ and $\gamma$. Including this term into the original Weinberg model gives the an anomaly free description for first generation leptons $(\nu, e)$ and the visible states of low energy QCD (and correctly describes $B + L$ violation, see [30]). Of course, this represents the effects of the underlying confined $(u, d)$ quarks. In our present situation we do not know what the underlying Weyl invariant UV complete theory of gravity and scalars is, but we can imitate the WZW term by demanding an overall Weyl invariant constraint that maintains the renormalization group (the $\phi$ loops).

The solutions to the constraint eqs.(104) are coupling constants that are functions of Weyl invariants. These clearly must be Lorentz scalars, and also invariant under general coordinate transformations (diffeomorphisms). In the single scalar theory, we only have at our disposal the Weyl invariant objects, $\phi^2 g_{\mu \nu}$, and $\phi^{-2} g^{\mu \nu}$, which are obviously not scalars. The quantity $\sqrt{g} \phi^4$ is Weyl invariant, but is a scalar density and not diffeomorphism invariant. This leaves the Ricci scalar, $R(\phi^2 g_{\mu \nu})$, expressed as a function of the invariant combination $g_{\mu \nu}$ where $g_{\mu \nu} = \phi^2 g_{\mu \nu}$ (and $g^{\mu \nu} = \phi^{-2} g^{\mu \nu}$):

$$R(\phi^2 g) = \phi^{-2} R(g) + 6 \phi^{-3} g^{\mu \nu} D_\mu \partial_\nu \phi \quad (105)$$

Therefore, we can consider the arguments of the logs to be a general functions $F_i[R(\phi^2 g)]$. The coupling constants become:

$$\lambda(\phi) = \frac{1}{2} \beta_\lambda \ln (F_\lambda [R(\phi^2 g)])$$

$$\alpha = 1 + (\alpha_0 - 1) (F_\alpha [R(\phi^2 g)])^{\alpha/2} \quad (106)$$

For example, we might choose:

$$F_i = \frac{c_i \phi^2}{R(g) + \frac{5}{6} g^{\mu \nu} D_\mu \partial_\nu \phi + c'_i \phi^2} \quad (107)$$

With the solutions of eqs.(101) we have the Weyl invariant Coleman-Weinberg effective action:

$$S = \int \sqrt{-g} \left( \frac{1}{2} g^{\mu \nu} \partial_\mu \phi \partial_\nu \phi - \frac{1}{4} \beta_\lambda \ln (F_\lambda [R(\phi^2 g), \phi^2]) \phi^4 \right. \left. - \frac{1}{12} \left( 1 + (\alpha_0 - 1) (F_\alpha [R(\phi^2 g), \phi^2])^{\alpha/2} \right) \phi^2 R \right) \quad (108)$$

The renormalization group equations eq.(99) are now modified:

$$F_{\lambda} \frac{\partial \lambda}{\partial F_{\lambda}} = \beta_\lambda$$

$$F_{\alpha} \frac{\partial \alpha}{\partial F_{\alpha}} = (\alpha - 1) \gamma_\alpha \quad (109)$$

In writing eq.(109) we have solved the constraint of eq.(104). Since this is a constraint, it only dictates that the functional form of the $F_i$, be Weyl invariant. In lieu of an exact calculation is at this stage, the $F_i$ arbitrary. However, such a calculation of the Coleman-Weinberg potential can be done (in a simple locally Weyl invariant two scalar theory) and it yields a specific functional form, as will be presented elsewhere [19].

We can specify $F_i$ if we match onto the calculated $\beta$-functions from $\phi$ loops For example, our choice in eq.(107) will be consistent with the computed $\beta$-functions of eq.(99) from $\phi$ loops, (but not necessarily with calculated functions associated with graviton loops). It is interesting to note that while $\beta_\lambda$ of eq.(99) produces a Landau pole in the running of $\lambda$ with large $\phi$, the choice of nonzero $c'_i \phi^2$ implies that asymptotically $\lambda(\phi)$ approaches a constant, $\lambda(c/c')$.

2. The Two Scalar Theory

In the case of the two scalar scheme, defined by eqs.(26,27), we have the five couplings, $(\lambda, \xi, \delta, \alpha_1, \alpha_2)$ and will have RG equations for running in $\phi$ or $\chi$. For the sake of discussion we will presently assume that the field VEV’s $\phi$ and $\chi$ are large compared to curvature $R$. If we consider a typical coupling constant $\lambda$ we therefore have the scale invariant constraint:

$$\frac{\partial \lambda}{\partial \phi} = \frac{\phi}{\chi} \frac{\partial \lambda}{\partial \chi} = 0. \quad (110)$$

We reinterpret the usual RG equations in terms of $\lambda(F)$ with running in a Weyl invariant function of $\phi$ and $\chi$, such as an arbitrary function of the ratio, $F_\chi = F(\phi/\chi)$, for example, $F = \phi/\chi$. The renormalization group $\beta$-function is now:

$$\beta_\lambda = F \frac{\partial \lambda}{\partial F} \quad (111)$$

Hence, we can maintain the Weyl symmetry while having $\beta$-functions that now describe the running of couplings in Weyl invariants. Elsewhere we will demonstrate how to obtain this result by a direct calculation of the Coleman-Weinberg effective potential while maintaining a local Weyl symmetry [19].

3. Relation to other scale invariant schemes

There have been several proposals for maintaining Weyl invariance that focus on the regularization schemes e.g., see [17, 22–27].

(i) Dimensional regularization. Extensively studied is the case of dimensional regularization in which the external mass scale, $\mu$ is replaced by a combination of fields, $\mu(\phi, \chi)$. In this approach the Coleman Weinberg formula for the 1-loop correction scalar potential:

$$- i \int d^4p \text{Tr} \ln \left[ \rho^2 - V(\phi, \chi) + i\epsilon \right] \quad (112)$$

6 There is a characteristic difference between RG running in field VEV’s and running in momentum space. E.g., the top quark, etc., never decouples if the Higgs VEV runs into the IR. RG running for deep scattering processes in momentum will be standard and remains sensitive to the Landau pole as usual.
is continued to d-dimensions. This gives:

\[ V(\phi, \chi) = \mu(\phi, \chi)^{4-d}V_0(\phi, \chi) \]  

(113)

where \( V_0(\phi, \chi) \) is the potential in 4D. The first factor gives additional corrections to \( V \) that, due to the divergent structure of the integral in 4D, give finite contributions to the scalar potential (see [26, 27]). Weyl invariance is maintained by choosing \( \mu \) to be a function of \( \phi \) and \( \chi \) of scaling dimension 1.

For the very simple choice \( \mu = \phi \) the resulting corrections are of the form \( \chi^2/\phi^2 + ... \) and the theory must be viewed as an effective field theory valid for \( \chi^2/\phi^2 \ll 1 \). Arbitrariness obviously enters here in the choice of \( \mu(\phi, \chi) \), and will affect the \( \beta \)-functions as we have discussed above.

(ii)“Renormalized” perturbation theory. In the case of renormalized perturbation theory the Feynman rules are derived from the Lagrangian computed in terms of the physical parameters of the theory. In this case the potential will have a dependence on the scale \( M \) at which the couplings are determined. Writing \( M \) as a function of \( \phi \) and \( \chi \) of scaling dimension 1, Weyl invariance can be maintained. However the field dependence of \( M = M(\phi, \chi) \) will, as in the case of dimensional regularization, give additional contributions to \( M^2 \) that give rise to non-renormalisable and arbitrary corrections of the form found in dimensional regularization.

(iii)“Bare” perturbation theory. An alternative possibility is bare perturbation theory in which the Feynman rules are based on the bare Lagrangian. In this case the bare potential has no dependence on the scale \( M \) and so there are no new contributions to the potential of the form discussed above. Weyl invariance can be maintained by identifying the cut-off scale, \( M \), in the loop calculations with a function of the fields of scaling dimension 1 and is equivalent to the procedure proposed in Section V C.

D. An ansatz for a quantum corrected theory

What might be the physical effects that arise from Weyl invariant renormalization? In the following we initially consider a general form, \( F(x) \) for the argument of the log and then specialise the case where \( F = x \). We shall see that this will lead to modifications during inflation to elliptic path in \((\phi, \chi)\) that we described above.

The one-loop CW action (neglecting terms in \( \delta \)) can then take the form of eq.(27) with the potential:

\[
W(\phi, \chi) \approx \frac{\lambda \phi^4}{4} + \frac{\beta_2}{4} \chi^4 \ln(cF(\phi/\chi))
\]

\[ = \frac{\lambda \phi^4}{4} \left[ 1 + \frac{\beta_2}{\lambda_3^4} \ln(cF(x)) \right] \]  

(114)

where \( x = \phi/\chi \) and \( c \) is a constant. A nontrivial minimum exists for the field values \( (\phi_0, \chi_0) \) if:

\[
\frac{\partial W}{\partial x} = 0 \rightarrow cF(x_0) = \exp(c_0F(x_0)/4F(x_0))
\]

\[
\frac{\partial W}{\partial \phi} = 0 \rightarrow 1 + \frac{\beta_2}{\lambda_3^4} \ln(cF(x_0)) = 0 \]  

(115)

Combining gives us one combination of the equations:

\[
1 \frac{F(x_0)}{\lambda_3^4} F(x_0) = -\frac{4\lambda}{\beta_2} \]  

(116)

An independent combination of the equations gives us a fine-tuning constraint on \( c \).

We can consider the simple case, \( F = F_2 = 1/x = \chi_0/\phi_0 \) and we thus find, \( x_0 = \phi_0/\chi_0 = (\beta_2/4\lambda)^{1/4} \). Note however the consistency condition, \( \ln(cF(x_0)) = -\lambda_3^4/\beta = -1/4 \) requires that \( c \) is fine tuned as: \( c = x_0 \exp(-1/4) \).

Before tuned, this not only corresponds to a minimum but also to a zero of the potential, i.e. a locus in field evolution of fixed \( x_0 = \phi_0/\chi_0 \) with no cosmological constant. It is straightforward to consider the more general case with a fixed point and late time accelerated expansion, generalizing the results we found in the previous sections.

Including a running \( \alpha_1 \) term and \( \alpha_2 \approx \text{constant} \), we have the action:

\[
S = \sqrt{-g} \left\{ \frac{1}{2} g^{\mu \nu} \partial_\mu \phi \partial_\nu \phi + \frac{1}{2} g^{\mu \nu} \partial_\mu \chi \partial_\nu \chi - W(\phi, \chi)
\]

\[ - \frac{1}{12} \left[ 1 + (\alpha_0 - 1) F(x) \right] |\phi^2 R - \frac{1}{12} \alpha_2 \phi^2 R \right\}. \]  

(117)

The quantum corrections deformed the ellipse shown in Fig.(2), arising from the running of the \( \alpha_1 \) (mainly \( \alpha_1 \) presently). \( \gamma_i \) is a parameter appearing in the \( \beta \)-function for \( \alpha_1 \), and \( \alpha_0 < 0 \) is an initial value of \( \alpha_1 \) at the “scale” \( \phi/\chi = 1 \). We reiterate that, in the Weyl invariant framework, one must get used to the notion that there are no fundamental mass scales anymore, and only invariant ratios of field VEV’s can arise in scale invariant physical quantities such as dimensionless couplings like the \( \alpha \).

Hence, given the fixed value of \( K \), we have in the classical and quantum cases:

\[
\text{classical:} \quad 2K = (1 - \alpha_1) \phi^2 + (1 - \alpha_2) \chi^2
\]

\[
\text{quantum:} \quad 2K = (1 - \alpha_{1q}) \phi^2 [F(x) \gamma] + (1 - \alpha_2) \chi^2
\]  

(118)

If we now specialise to \( F(x) = F_2 = x \), we find the differences illustrate in Fig.(3). In this case, the Planck mass is now given by:

\[
\text{classical:} \quad 6M_{\text{Pl}}^2 = -\alpha_1 \phi^2 - \alpha_2 \chi^2
\]

\[
\text{quantum:} \quad 6M_{\text{Pl}}^2 =
\]

\[ - \left( 1 - (1 - \alpha_{1q}) \left( \frac{\phi}{\chi} \right)^\gamma \right) \phi^2 - \alpha_2 \chi^2 \]  

(119)
thus we see that at the end of the ellipse with $\chi \to 0$:

$$M_P^2 = \frac{1}{6} \left( (1 - \alpha_{10}) \left( \frac{\phi}{\chi} \right) \gamma \right) \phi^2 = \frac{1}{3} \gamma$$  \hfill (123)

While $\phi$ and $\chi$ are becoming smaller, they do not become zero. The fixed point, the terminus of inflation, corresponds to the minimum of the potential in the flat direction, hence

$$\chi = \varepsilon \phi$$  \hfill (124)

Combining, this yields the final VEV's of the fields:

$$\phi = M_P \left( \frac{6 \varepsilon \gamma}{1 - \alpha_{10}} \right)^{1/2} \chi = \zeta \phi$$  \hfill (125)

It is interesting to speculate about the implications of this result in realistic models. The present model supposes only the potential interactions amongst $\phi$ and $\chi$ and the non-minimal gravitational interactions. The quantities $\gamma$ in the present scheme are determined by the quartic couplings $\lambda, \delta, \zeta$ and involves mixing induced by $\delta$. If the only relevant term was $\lambda$, as in the single scalar model, we compute $\gamma = 3\lambda/8\pi^2$. However, with the flat direction we have $\lambda = -2\gamma \delta$, and mixing effects in $\gamma$ are dominant. In any case, if the potential coupling contributions to $\gamma$ are small and if they are the only effects, we would have the classical result, $\phi = c_0 M_P$ with $c_0 = \sqrt{6/(1 - \alpha_{10})}$ of order unity.

However, other schemes would likely have additional interactions, including gauge interactions. For example, $\phi$ and $\chi$ could have separate $U(1)$ gauge groups and gauge couplings $(e_1, e_2)$, hence $\gamma = ke_1^2/16\pi^2$. Moreover, what is relevant is the "UV" behaviour of these couplings i.e., the large $\phi/\chi$ limit, and they could become large. Hence, is possible that in such schemes $\gamma_1$ can become large, perturbatively ranging, perhaps, from $\sim 0.1$ to 1, and nonperturbatively even larger. We thus would have $\phi = c_0 M_P e^{\gamma/2}$ and:

$$\phi = c_0 M_P e^{\gamma/2} \chi = \zeta \phi$$  \hfill (126)

If we then identify $\chi$ with the Higgs VEV, $v_H = 175$ GeV, then we determine $\phi = c_0 M$ where $M = 2.6 \times 10^{13}$ GeV with $\gamma = 1$ and $M = 1.8 \times 10^{18}$ GeV with $\gamma = 0.1$. So, it possible that the quantum running of $\alpha_{10}$ plays a role in establishing the grand unification scale, identified with the VEV of $\phi$. Even more extreme, if we identify $\chi$ with the QCD scale, 0.1 GeV and allow a nonperturbative at large $\phi/\chi$, $\gamma \approx 10$, then we find $\chi \approx v_H \approx 175$ GeV. Perhaps $\chi$ could then be identified with the Higgs boson itself (this would be a "Higgs inflation model" with a dynamically generated Planck mass), where $M_P \sim m_H (m_H/\Lambda_{QCD})^2$.

The quantum effects are clearly of great interest. A detailed study of the renormalization of this theory and various models is beyond the scope of the present paper (see [19]). In particular the worked example of the ellipse we have presented involves a particular choice of an "ansatz" of $F(\chi)$ that might be anticipated from full calculation. Full details will be presented elsewhere [19].
VI. CONCLUSIONS

In the present paper we have discussed how inflation and Planck scale generation emerge from a dynamics associated with global Weyl symmetry and its current, $K_\mu$. In the pre-inflationary universe, the scale current density, $K_0$, is driven to zero by general expansion. However, $K_\mu$ has a kernel structure, i.e., $K_\mu = \partial_\mu K$, and as $K_0 \to 0$, the kernel evolves as $K \to$ constant. This resulting constant K defines the scale symmetry breaking, indeed, defines $M_\beta^2$. The breaking of scale symmetry is thus determined by random initial values of the field VEV’s. In addition, a scale invariant potential of the theory ultimately determines the relative VEV’s of the scalar fields contributing to $K$.

This mechanism entails a new form of dynamical scale symmetry breaking driven by the formation of a nonzero kernel, $K$, as the order parameter of scale symmetry breaking. The scale breaking has nothing to do with the potential in the theory, but is dynamically generated by gravity. The potential ultimately sculpts the structure of the vacuum (together with any quantum effects that may distort the $K$ ellipse). There is a harmless dilaton associated with the dynamical symmetry breaking.

We illustrated this phenomenon in a single scalar field theory, $\phi$, with non-minimal coupling to gravity $\sim -\frac{1}{12}\alpha \phi^2 R$, and a $\lambda \phi^4$ potential. The theory has a conserved current, $K_\mu = (1 - \alpha) \phi \partial_\mu \phi$. The scale current charge density dilutes to zero in the pre-inflationary phase $K_0 \sim (a(t))^{-3}$. Hence, the kernel, $K = (1 - \alpha) \phi^2 / 2$, and the VEV of $\phi$ are driven to a constant. With $\alpha < 0$, this induces a positive Planck (mass)$^2$. The resulting inflation is eternal. However, if we allowed for breaking of scale symmetry through quantum loops, by conventional scale breaking renormalization, the resulting trace anomaly would imply that $K_\mu$ is no longer conserved. Then $\phi$ would relax to zero, and so too the Planck mass.

In multi-scalar-field theories we see that the generalized $K = \sum_i (1 - \alpha_i) \phi_i^2 / 2$. As this is driven to a constant by gravity, it defines an ellipsoidal constraint on the scalar field VEV’s, and the Planck scale is again generated by $K$. An inflationary slow-roll is then associated with the field VEV’s migrating along the ellipse, ultimately flowing to an infra red fixed point. This is shown to be amenable to analytic treatment, again owing to the Weyl symmetry. If the potential has a flat direction, which is a ray in field space that intersects the ellipse, then the fixed point corresponds to the potential minimum, and the field VEV’s flow to it. This is associated with a period of rapid reheating and relaxation to the vacuum. This terminal phase of inflation is similar to standard $\phi^4$ inflation, since the effective theory is now essentially Einstein gravity with a fixed $M_\beta^2$. The vacuum is determined by the intersection of the flat direction and the ellipse. The final cosmological constant vanishes by the scale symmetry.

These classical models illustrate the essential requirement of maintaining the Weyl symmetry, including quantum effects throughout. Any Weyl breaking effect will show up as a nonzero divergence in the $K_\mu$ current. Quantum anomalies will occur with conventional running coupling constants ($\beta$-functions). We show that a Weyl invariant condition can be imposed on renormalized coupling constants to enforce the symmetry in the renormalized action. The coupling “constants” are then functions of Weyl invariant quantities. For example, $\lambda$, which previously ran with $\phi / M$, now runs with the Weyl invariant function of the fields, $F_k(\phi, \chi, g_{\mu \nu})$. This preserves all of the features of the classical global Weyl invariant model, but enforces a constraint on the original $\beta$-functions that can only be satisfied by introducing field dependent counterterms. This is similar to adding the Wess-Zumino-Witten term to a theory as a counterterm to cancel (or provide) unwanted (or desired) chiral anomalies. We will explore detailed calculations that explicitly exhibit these results elsewhere [19].

We have experimented with the anticipated effects of quantum corrections in a simple ansatz model of the quantum effects. Here we see that the ellipse may be significantly distorted near the intersection with a potential flat direction. The final phase of inflation can involve a trajectory in which both scalar field VEV’s shrink, but subject to a constraint that maintains constant $K$, and thus constant $M_\beta^2$. If the quantum effects are large, we may generate multiple hierarchies with possibly intriguing relationships, such as $M_P = M_{\text{GUT}} (M_{\text{GUT}} / m_{\text{Higgs}})^7$.

The Nambu-Goldstone theorem applies in these models, with the dynamical scale symmetry breaking by nonzero $K$, and there is a dilaton. We touch upon some of the properties of the dilaton, with a more detailed discussion of its phenomenology in a subsequent work [19]. If the underlying exact Weyl scale symmetry (though spontaneously broken via $K$) is maintained throughout the theory, then the massless dilaton has at most derivative coupling to matter, becomes harmlessly decoupled, and any putative Brans-Dicke constraints go away [32]. Again, here it is essential that quantum breaking of global Weyl scale symmetry be suppressed to maintain the decoupling of the dilaton.

An unsolved problem in these schemes is that the flat direction generally can exist only for the special case of a fine-tuned parameter. This has been argued to be enforced in certain cases by a symmetry, such as in an $SO(1,1)$ invariant potential, $\sim \lambda (\phi^2 - \chi^2)^2$ [5]. However, there is no such symmetry in the full theory as, e.g., the $\phi$ and $\chi$ kinetic terms are $O(2)$ invariant, and these symmetries will clash in loop order, and the flat direction will be lifted. If $\epsilon$ is not fine-tuned, then we get either a trivial minimum at $\phi_0 = \chi_0 = 0$, or a saddle-point. Hence, a fundamental problem for us is how to naturally maintain flat directions.

Though we haven’t discussed it in detail presently, we expect there are implications here for novel UV completions of gravity. There is an inherent UV “softening” of quantum general relativity in these schemes since, essentially, we have no graviton propagator in this theory until the Planck scale forms. The low energy Einstein gravity is then emergent. The UV completion of gravity would have to be scale-free and it might be viewed as a theory that contains only a metric, matter fields with non-minimal couplings, general covariance, but no stand-alone curvature terms. The construction of such a theory is beyond the scope of the present paper.
Global Weyl invariance may be a veritable and profound constraint on nature. It hints at intriguing consequences, dramatically including a dynamical origin of inflation and $M_p$ as a unified phenomenon, dynamically generated mass hierarchies, including new effects that involve the running to the Planck scale with non-minimally coupled scalars, including Coleman-Weinberg potentials. The authors find it challenging to construct viable models, lending support to the result here that Weyl symmetry must be maintained and its breaking can only be spontaneous.

[20] S. Weinberg, “Gravitation and Cosmology,” Wiley and Sons, (1972); the Riemann-Christoffel tensor is defined in Weinberg’s eq.(6.1.5); this sign is opposite to that in common use, e.g., as given in R. Wald, “General Relativity,” University Of Chicago Press (1984). Both Weinberg and Wald use the metric signature convention $(−1, 1, 1, 1)$. Ref.([21]) uses the Weinberg definition of curvature, but adopts the metric signature $(1, -1, -1, -1)$. In the present paper we follow the conventions of ref.([21]).
