Supplement of

On the shape of forward transit time distributions in low-order catchments

Figures S1 to S12
Tables S1 to S12

Introduction

The supplement consists of 8 sections, 12 figures and 12 tables. The individual sections contain a comparison of TTDs resulting from different dispersivity values (S1, Fig. S1, Table S1), a comparison of TTDs resulting from a looped and a continuous precipitation time series (S2, Fig. S2), an overview of the different modeling scenarios (Table S2), the precipitation time series created for testing the influence of the sequence of events (Fig. S3) and the table containing all distributions metrics for those 15 scenarios (Table S3), a comparison of different theoretical probability density functions (Fig. S7), information on TTD smoothing (S5, Fig. S8), the derivation of TTDs from tracer breakthrough curves (Fig. S9), the analysis of spatial tracer distribution over the catchment and in its profile (S6, Fig. S10), outflow probability distributions plotted against cumulative outflow (Fig. S11), measures of how well the different theoretical probability distributions fit the modeled TTDs (Table S5), metrics of the TTDs derived from scenarios with other catchment and climate properties (Tables S6 to S12), a method to add power-law tails to gamma probability distributions (S7, Fig. S7) as well as an example of using TTDs for reactive solute transport applications (S8, Fig. S12).

S1

In order to rule out that a smaller model value for the longitudinal dispersivity \( \alpha_L \) would influence our results significantly, we set up two additional runs. In these runs we reduced \( \alpha_L \) by 1 order of magnitude from 5 m to 0.5 m. We chose to test the two scenarios THWB and TLDS since they result in the longest and shortest transit times of all model scenarios, respectively. We found only small deviations for TLDS in the early part of the TTD (with none of the transit time quartiles being more than five percent longer than in the reference case with larger \( \alpha_L \)) and virtually no difference for THWB (Fig. S1 and Table S1).

S2

We looped a 1-year-long time series of precipitation from the northeast of Germany and used it as a boundary condition throughout the 33-year-long model period in all of the scenarios. In order to check whether the looping would cause any unwanted artifacts in the resulting TTDs we additionally created a 32-year-long synthetic continuous precipitation time series with similar attributes: average yearly precipitation amount of 690 mm a\(^{-1}\), average event interarrival time of 2.64 days and Poisson distributed precipitation event amounts. This continuous (non-looped) time series was attached to the 1-year-long recorded time series to create a second 33-year-long time series. The comparison of the two resulting TTDs shows that the looping does not introduce any artifactual irregularities into the TTD shape (Fig. S2).

S3

1. The first quartile (Q\(_1\)) was determined via the cumulative TTD. It is the transit time when 25 % of the applied tracer mass has left the system.
2. The median (Q\(_2\)) was derived similarly (when 50 % of the applied tracer mass has left the system).
3. The mean transit time (mTT):
   \[ mTT = \Sigma(J_{out}^{norm} \ast \Delta t \ast t). \]  
   \[(S1)\]
4. The third quartile (Q\(_3\)) was again determined with the help of the cumulative TTD (when 75 % of the applied tracer mass has left the system).
5. The standard deviation (\( \sigma \)) is a measure describing the dispersion of a distribution, with a small standard deviation pointing towards the data point cloud being clustered closely around the mean:
   \[ \sigma = \sqrt{\Sigma(J_{out}^{norm} \ast \Delta t \ast t^2) - mTT^2}. \]  
   \[(S2)\]
6. The skewness (\( \gamma \)) is a measure that informs about how much a distribution leans to one side of its mean. A negative skew means that the distribution leans towards the right (the highest concentration follows after the mean), a positive skew indicates that the distribution leans towards the left (the highest concentration is reached before the mean):
   \[ \gamma = \Sigma(J_{out}^{norm} \ast \Delta t \ast (t - mTT)^3) - 3. \]  
   \[(S4)\]
7. The excess kurtosis (\( \gamma \)):
   \[ \gamma = \Sigma(J_{out}^{norm} \ast \Delta t \ast (t - mTT)^4) - 3. \]  
   \[(S4)\]

A positive excess kurtosis means that a distribution produces more extreme outliers than the Gaussian normal distribution, so this measure is related predominantly to the tail of the distribution – and only to a lesser extent to its peak. For positive values of the excess kurtosis, the tail of the distribution approaches zero more slowly than a normal distribution while the peak is higher (leptokurtic). For negative values of the excess kurtosis, the tail approaches zero faster than a
normal distribution while the peak is lower (platykurtic). There is no unanimous consent on the mathematical definition of what constitutes a “heavy” or “light” tail. According to some sources heavy tails are those tails that have more weight than an exponential tail – a definition which corresponds to heavy-tailed distributions being defined as possessing an increasing hazard (rate) function (Kellison and London, 2011). This definition would place gamma distributions with shape parameters $\alpha < 1$ clearly in the category of heavy-tailed distributions and gamma distributions with shape parameters $\alpha > 1$ in the category of light-tailed distributions. Other sources, however, attribute heavy tails only to distributions with infinite moment generating functions (Rolski et al, 2009). Therefore we are not using the (absolute) terms heavy-tailed or light-tailed to describe the TTDs but rather just refer to “heavier” and “lighter” tails in the manuscript.

S4

We calculated young water fractions for the best-fit gamma distributions to see how they are influenced by catchment and event properties. The young water fraction ($F_{yw}$) constitutes the fraction of water in discharge with an age between 0 and a ‘humped’ shape causing less outflow at short transit times. In general, $F_{yw}$ increases with increasing $P_{sub}$, $\theta_{sat}$, $K_s$ and with decreasing $D_{soil}$ (Fig. S6). The highest $F_{yw}$ was observed for scenarios with shallow $D_{soil}$, wet $\theta_{sat}$ and large $P_{sub}$. The increase with increasing $\theta_{sat}$ is found because catchment soil storage is already filled and hydraulic conductivity of the soil is already high (close to saturation) so that the incoming event water can immediately flow laterally towards the outlet while only a smaller fraction stays in the soil storage or enters the low-conductivity bedrock. In catchments with higher $K_s$, $F_{yw}$ also increases since the conductivity contrast between the bedrock and the soil increases and more of the incoming event water flows laterally towards the outlet with a higher velocity. Shallow soils increase $F_{yw}$ too due to the fact that less soil storage is available where event water can be stored before lateral flow is initiated. Finally, larger $P_{sub}$ increases $F_{yw}$ as well, which can be associated with the “flushing effect” where more flow in the more fully saturated soil layer equals a larger flux through the soil layer and hence a larger fraction of young water in the discharge.

S5

The modeled TTDs where smoothed just for the purpose of better visual comparison – all the calculations and the fitting were performed on the unsmoothed data (see Fig. S8 for an example of a smoothed TTD). We smoothed the TTDs by using moving window averaging with increasing window size towards longer transit times:

$$N_{left}(t) = \begin{cases} N, & \text{if } (ln t)^3 \leq 0 \\ \left\lfloor (N(t) - 0.5(ln t)^3) \right\rfloor, & \text{if } (ln t)^3 > 0 \end{cases}$$ (S5)

$$N_{right}(t) = \begin{cases} N, & \text{if } (ln t)^3 \leq 0 \\ \left\lceil (N(t) + (ln t)^3) \right\rceil, & \text{if } (ln t)^3 > 0 \end{cases}$$ (S6)

with $N_{left}$ being the model time step number at the left corner of the window, $N_{right}$ the model time step number at the right corner of the window and $N$ the model time step number at a given transit time $t$. We increased the window size with increasing transit time since we plotted the TTDs on a double–log scale so that the older parts of the TTDs were compressed and also because the variation in the initial shape of the TTD is higher and influenced more by the series of subsequent precipitation events.

S6

Comparing the evolution of tracer concentrations throughout the model domain can explain the differences of the resulting TTDs for the various model scenarios. Figure S10 demonstrates this by showing tracer concentrations at the soil surface and in a depth profile close to the center of the catchment for two very different scenarios (FHWB with the shortest median and mean transit time and TLDS with the longest median and mean transit time). The fast arrival of the tracer in the FHWB scenario is possible since the tracer quickly infiltrates the entire soil column and is transported laterally towards the outlet. In the TLDS scenario it takes much longer for the entire soil column to act as a pathway for lateral flow which is partly due to the fact that $\theta_{sat}$ is low (more pore space can be filled up until saturated hydraulic conductivity is reached and more pore space is available to be filled up before water will be diverted downslope at the bedrock–soil interface). Both TTDs peak after the entire soil column is filled with tracer and starts acting as a lateral flow path and some tracer has entered the bedrock. This happens almost instantly in the FHWB scenario and only after approximately 100 days in the TLDS scenario. The amount of tracer infiltrating into the bedrock is higher for the TLDS scenario. This is due to the fact that the contact time between tracer in the soil and the bedrock surface is longer. In the FHWB scenario the tracer is flushed out of the soil a lot faster (higher $K_s$ and more $P_{sub}$), therefore less tracer can infiltrate into the bedrock. The soil in the FHWB scenario is virtually free of tracer much sooner than the soil in the TLDS scenario, therefore the break in the tail of the TTD (deriving from the switch from predominantly soil to predominantly bedrock tracer outflux) happens earlier than for the TLDS scenario (around 1000 days vs. around 5000 days).
days). The tail is heavier for TLDS since more tracer had the chance to infiltrate into the bedrock at later times.

**S7**

Adding power-law tails to gamma distributions can be done via a simple approach that replaces the tail of the respective distribution with a power-law tail as soon as the probability density of the model distribution falls below that one of a power law with a constant \( a \) of 0.2 and an exponent \( k \) of 1.6 (Fig. S7):

\[
f(t) =
\begin{cases}
\frac{t^{\alpha-1}}{\beta^{\alpha \Gamma(\alpha)}} e^{-\frac{t}{\beta}} & \text{if } \frac{t^{\alpha-1}}{\beta^{\alpha \Gamma(\alpha)}} \geq at^{-k} \vee t \leq \alpha \beta \\
at^{-k} & \text{if } \frac{t^{\alpha-1}}{\beta^{\alpha \Gamma(\alpha)}} < at^{-k} \wedge t > \alpha \beta
\end{cases}
\]

(S7)

In order to preserve the mass balance, the combined distribution has to be re-normalized (accounting for the added mass from the power-law tail):

\[
w = \int_{t=0}^{\infty} f(t).
\]

(S8)

\[
TTD(t) = \frac{f(t)}{w}.
\]

(S9)

From a mass balance perspective, however, generally it is not necessary to add these power-law tails since they only account for a very small fraction of the total injected mass. Yet they can alter the mTT significantly (while the median remains largely unaffected).

**S8**

Modification of TTDs to incorporate reactive solute transport into the concept can be achieved, for example, by multiplication of the TTD with a decay function. In this example an exponential decay function is used:

\[
TTD_{rx}(t) = TTD(t) \ast e^{-t/t_{1/2}},
\]

(S10)

where TTD(t) is the probability density at transit time \( t \) and \( t_{1/2} \) is the half-life of the solute. Note that the cumulative TTD \( r_x \) does not add up to a value of 1 anymore. It rather reflects the fraction of solute that will eventually be discharged out of the catchment (Fig. S12).

Other functions that can modify TTDs to make them suitable predictors of reactive solute transport include specific retardation or removal functions for certain transit time ranges associated with flow paths through different catchment compartments (for example, groundwater flow, soil matrix flow, macropore flow).
Figure S1. Comparison of TTDs derived from scenarios with large and small longitudinal dispersivity $\alpha_L$. Differences are small, in particular for the scenario with high hydraulic soil conductivity (THWB).

Figure S2. Comparison of TTDs derived from a continuous and from a looped 1-year-long precipitation time series. Looping does not cause artifacts and there is no significant difference between the two TTD shapes.

Figure S3. 15 different precipitation time series with similar exponential distributions of precipitation event amounts and interarrival times. The y axes all range from 0 to 40 mm. The time series were created to test the influence of event sequence on the shape of TTDs.

Figure S4. (a) Total tracer mass in storage, (b) cumulative tracer mass outflux, (c) cumulative mass balance error for all 36 scenarios. Note that most scenarios plot on top of each other in (c).
Figure S5. Distribution metrics of three different gamma distributions with varying shape parameter $\alpha$ and equal mean (300 h). (a) Black dashed line: mean (300 h), dotted black line and filled areas under the curves: standard deviation. (b) Black dashed line: mean (300 h), colored dashed lines: medians, filled areas under the curves range from the first to the third quartile ($Q_1$–$Q_3$).

Figure S6. Change of young water fractions ($F_{yw}$) with the flow path number ($F$) for four different catchment and climate properties. Yellow colors indicate dry, green intermediate and blue wet $\theta_{ant}$. Thick marker lines indicate big, mid-sized lines medium and thin lines small amounts of $P_{sub}$. Solid lines indicate low, dashed lines high $K_s$, lighter shades of a color indicate shallow, darker shades deep $D_{soil}$. 
Figure S7. A set of ten different common theoretical probability distributions (all but the power law having a mean value of 300 h, grey line). The black dotted line is a distribution that is a combination of a gamma distribution with the tail of a power-law distribution. The inset has a log–log scale.

Figure S8. Unsmoothed (orange) and smoothed (black) version of the same TTD.

Figure S9. Precipitation input (cyan), total outflow (blue) and tracer mass outflux (red) for the first 3 years of the model run for scenario THDM. The normalized tracer breakthrough curve constitutes the TTD of the injected tracer impulse.

Figure S10. Time series of tracer concentration distribution in the subsurface across the entire catchment, in a depth profile in the center of the catchment for two scenarios (top: FHWB; bottom: TLDS) with very different resulting TTDs shapes. The dotted black line in the profiles represents the soil–bedrock interface; the white dashed line is the water table.
Figure S11. Similar to Fig. 7 except for the fact that outflow probability is plotted against cumulative outflow instead of transit time. Distributions are grouped by soil depth (a and b = deep (thick); c and d = shallow (flat)) and saturated hydraulic conductivity (a and c = high; b and d = low). Yellow colors indicate dry, green intermediate and blue wet $\theta_{ant}$. Thick lines indicate big, mid-sized lines medium and thin lines small $P_{mbc}$. Dashed black lines divide TTDs into four parts, each part controlled by different properties. Note the log–log axes. Insets show cumulative outflow probability distributions.

Figure S12. Two TTDs from the FHWB (blue) and TLDS (yellow) scenarios. Each one modified by three functions of exponential decay (with half-lives $t_{1/2}$ of 10, 100 and 1000 days). The fraction of mass eventually leaving the system ($%M$) can differ greatly: for a half-life of 100 days, the FHWB TTD still delivers 59% of the original input to discharge while the TLDS TTD only delivers 2%.
Table S1. Metrics of the TTDs for the simulations with larger (5 m) and smaller (0.5 m) values of the longitudinal dispersivity $\alpha_L$. All times are given in days.

| Name | THWB | TLDS |
|------|------|------|
|      | Large | Small | Large | Small |
| First quartile | 45 | 45 | 458 | 462 |
| Median | 85 | 86 | 785 | 810 |
| Mean | 110 | 109 | 1009 | 1037 |
| Third quartile | 136 | 136 | 1308 | 1369 |
| SD | 173 | 172 | 880 | 905 |

Table S2. Information on which of the base-case scenarios (upper table) the other scenarios are based upon (dispersivity – italic; porosity – blue; bedrock conductivity – orange; decay in hydraulic conductivity – red; precipitation frequency – green; catchment shape – bold; soil water retention curve – purple; extreme precipitation after full saturation – yellow).

Table S3. Young water fractions ($F_{yw}$) for the 36 different base-case scenarios. The young water fractions are determined from the best-fit gamma distributions ($F_{yw \, Gam}$) and from the modeled TTDs themselves ($F_{yw \, Mod}$).

Table S4. Distribution metrics for the 15 TTDs resulting from different precipitation event sequences. For comparison we also show the metrics for the THDM scenario which uses an actually measured time series of precipitation and has a slightly different distribution of precipitation event amounts and interarrival times but otherwise similar catchment and climate properties. The means ($\mu$) and standard deviations ($\sigma$) of the metrics of the 15 scenarios are also shown. All times are given in days.
Table S5. Deviations of mean (green) and median (blue) transit times between the best-fit theoretical probability distributions and the modeled TTDs. Sum of the squared residuals (yellow) indicating goodness of fit between theoretical probability distributions and modeled TTDs. All times are given in days.

**Table S11.** Metrics of the TTDs derived from simulations with different catchment shapes (top-heavy, bottom-heavy). ‘Mid’ refers to the basic oval shape. All times are given in days.

**Table S12.** Metrics of the TTDs derived from simulations with wet (W) or fully saturated (S) antecedent moisture conditions and very large (+, 10 mm h⁻¹) or extreme (+++, 100 mm h⁻¹) event precipitation. The percentage of overland outflow during the first 10 days (% SOF₀,10) is also listed. All times are given in days.
