Investigation of hadronic transitions between heavy quarkonia is a key source of information necessary for understanding Quantum Chromodynamics (QCD). Heavy quarkonium systems are in general nonrelativistic and hadronic transitions for the lower-lying states have largely been successfully described using the QCD multipole expansion model [1].

New aspects of hadronic transitions between heavy quarkonia have been explored using a data sample collected with Belle at the \(\Upsilon(10860)\) resonance peak. The anomalously large width of the \(\Upsilon(10860) \rightarrow \pi^+\pi^-\Upsilon(mS)\) \((m = 1, 2, 3)\) and \(\pi^+\pi^- h_b(nP)\) \((n = 1, 2)\) transitions has been interpreted within various QCD models [3] as either due to the rescattering of the B mesons [4] or due to the existence of a tetraquark state, \(Y_b\), with a mass close to that of the \(\Upsilon(10860)\) resonance [5]. A detailed analysis of the three-body \(e^+e^- \rightarrow \pi^+\pi^-\Upsilon(mS)\) and \(e^+e^- \rightarrow \pi^+\pi^- h_b(nP)\) processes reported by Belle [6] revealed the presence of two charged bottomonium-like states, denoted as \(Z_{b_1}(10610)^\pm\) and \(Z_{b_0}(10650)^\pm\). A similar investigation of \(\pi^+\pi^-\pi^0\) hadronic transitions between the \(\Upsilon(10860)\) and \(\chi_{bJ}\) \((J = 0, 1, 2)\) may offer additional insight into strong interactions in heavy quarkonium systems.

The observation of the \(X(3872)\) in 2003 revealed that the meson spectroscopy is far more complicated than the naive expectation of the quark model. It is therefore natural to search for a similar state with \(J^{PC} = 1^{++}\) (called \(X_b\) hereafter) in the bottomonium system [8, 9]. The search for \(X_b\) supplies important information about the discrimination of a compact multiquark configuration and a loosely bound hadronic molecule configuration for the \(X(3872)\). The existence of the \(X_b\) is predicted in both the tetraquark model [10] and those involving a molecular interpretation [11-13].

PACS numbers: 13.25.Gv, 14.40.Pq, 14.40.Rt, 12.38.Qk
cently, the CMS Collaboration reported a null search for such a state in the $\pi^+\pi^-\Upsilon(1S)$ final state [14]. However, unlike the $X(3872)$, whose decays exhibit large isospin violation, the $X_b$ would decay preferably into $\pi^+\pi^-\pi^0\Upsilon(1S)$ rather than $\pi^+\pi^-\eta\Upsilon(1S)$ if it exists [12, 13, 17].

In this Letter, we study the $e^+e^- \rightarrow \pi^+\pi^-\pi^0\chi_{bJ}$ ($J = 0, 1, 2$) processes with subsequent $\chi_{bJ} \rightarrow \gamma\Upsilon(1S)$, $\Upsilon(1S) \rightarrow \ell^+\ell^- (\ell = e \text{ or } \mu)$ decays. As the $X(3872)$ was observed in $e^+e^- \rightarrow \gamma X(3872)$ at center-of-mass energies around 4.26 GeV [18], we also search for an $X(3872)$-like state $X_b$ decaying to $\omega\Upsilon(1S)$ with $\omega \rightarrow \pi^+\pi^-\pi^0$ in $e^+e^- \rightarrow \gamma X_b$ at higher energies. The results are based on a 118 fb$^{-1}$ data sample collected with the Belle detector at $\sqrt{s} = 10.867$ GeV. The Belle detector [19] operates at the KEKB asymmetric-energy $e^+e^-$ collider [20].

The EVTGEN [21] generator is used to simulate Monte Carlo (MC) events. For the two-body decays $e^+e^- \rightarrow \omega\chi_{bJ}$ and $e^+e^- \rightarrow \gamma X_b$ at $\sqrt{s} = 10.867$ GeV, the angular distributions are generated using the formulae in Ref. [22]. The $X_b$ is assumed to have a mass of 10.6 GeV/c$^2$ and a negligible width in the MC simulation. Other masses and widths are taken from Ref. [23].

For charged tracks, the impact parameters perpendicular to and along the positron beam direction (the $z$ axis) with respect to the interaction point are required to be less than 0.5 cm and 3.5 cm, respectively, and the transverse momentum is restricted to be higher than 0.1 GeV/c. A likelihood $L_p$ for each charged track is obtained from different detector subsystems for each particle hypothesis $P \in \{ e, \mu, \pi, K, p \}$. Tracks with a likelihood ratio $R_K = L_K/(L_K + L_\pi) < 0.4$ are identified as pions [24] with an efficiency of 96%, while 4% of kaons are misidentified as pions. Similar likelihood ratios $R_e$ and $R_\mu$ are defined for electron and muon identification [25]. The charged track is accepted as an electron/positron if $R_e > 0.01$ or as a muon if $R_\mu > 0.1$. The lepton pair identification efficiency is about 95% for $\Upsilon(1S) \rightarrow e^+e^-$ and 93% for $\Upsilon(1S) \rightarrow \mu^+\mu^-$. Events with $\gamma$ conversion are removed by requiring $R_\gamma < 0.9$ for the $\pi^+\pi^-$ candidate tracks. Final state radiation and bremsstrahlung energy loss are recovered by adding the four-momentum of photons detected within a 50 mrad cone around the electron or positron flight direction in the $e^+e^-$ invariant mass calculation. The $\Upsilon(1S)$ candidate is reconstructed from a pair of oppositely-charged leptons.

A neutral cluster in the electromagnetic calorimeter is reconstructed as a photon if it does not match the extrapolated position of any charged track and its energy is greater than 50 MeV. To calibrate the photon energy resolution function, three control channels $D^{\ast}\rightarrow \gamma D\rightarrow K^-\pi^+$, $\pi^0\rightarrow \gamma\gamma$ and $\eta\rightarrow \gamma\gamma$ are used [26]. A $\pi^0$ candidate is reconstructed from a pair of photons. We require $M(\gamma\gamma)$ within $\pm 13$ MeV/c$^2$ of the $\pi^0$ nominal mass as the signal region and the non-$\pi^0$ backgrounds ($\pi^0$ sidebands) are defined as $0.08 \text{ GeV/c}^2 < M(\gamma\gamma) < 0.115 \text{ GeV/c}^2$ or $0.155 \text{ GeV/c}^2 < M(\gamma\gamma) < 0.18 \text{ GeV/c}^2$.

To improve the track momentum and photon energy resolutions and to reduce the background, a five-constraint (5C) kinematic fit is performed, where the invariant mass of the two leptons is constrained to the $\Upsilon(1S)$ nominal mass [23] and the energy and momentum of the final-state system are constrained to the initial $e^+e^-$ center-of-mass system. The $\chi_{bJ}^{2}/\text{dof}$ value is required to be less than 5 for both $\Upsilon(1S) \rightarrow \ell^+\ell^-$ modes with an efficiency of 85%. Here, dof = 5 is the number of degrees of freedom. This requirement removes events with one or more additional or missing particles in the final states. If there are multiple combinations for a candidate event, the one with the smallest $\chi_{bJ}^{2}/\text{dof}$ is retained.

The $\chi_{bJ}$ candidates are reconstructed from a candidate $\Upsilon(1S)$ and a photon. The $\Upsilon(1S)$ invariant mass distribution after event selection is shown in Fig. 1 where the shaded histogram is from the normalized non-$\pi^0$ background events. Clear peaking signals in the $\chi_{bJ}^{2}/\text{dof}$ sidebands, defined as $15 < \chi_{bJ}^{2}/\text{dof} < 25$: no $\chi_{bJ}$ peaks in the $M(\gamma\Upsilon(1S))$ distribution are found for such events.

After the application of all of the selection requirements, the remaining background comes mainly from non-$\pi^0$ events that are represented by the $\pi^0$ sidebands or possibly a subdominant non-$\chi_{bJ}$ background. To probe for other peaking backgrounds, a 89.4 fb$^{-1}$ continuum data sample collected at $\sqrt{s} = 10.52$ GeV and inclusive $\Upsilon(10860)$ decays generated with PYTHIA [27] with three times the luminosity of the data are analyzed. Moreover, MC samples of $\Upsilon(10860) \rightarrow \eta\Upsilon(2S) \rightarrow \gamma\gamma\pi^+\pi^-\Upsilon(1S)$, $\Upsilon(10860) \rightarrow \pi^+\pi^-\Upsilon(2S) \rightarrow \pi^+\pi^-\pi^0\pi^0\Upsilon(1S)$, $\Upsilon(10860) \rightarrow \pi^0\pi^0\Upsilon(2S) \rightarrow \pi^+\pi^+\pi^0\pi^-\Upsilon(1S)$, $\Upsilon(10860) \rightarrow \pi^+\pi^-\Upsilon(2S) \rightarrow \pi^+\pi^+\gamma\chi_{b1} \rightarrow \pi^+\pi^-\gamma\Upsilon(1S)$ and $\Upsilon(10860) \rightarrow \pi^+\pi^-\Upsilon(1D) \rightarrow \pi^+\pi^-\gamma\chi_{b1} \rightarrow \pi^+\pi^-\gamma\Upsilon(1S)$ are generated and analyzed: no structures in the $\gamma\Upsilon(1S)$ invariant mass spectrum are seen in these samples after applying all of the selection criteria.

![Figure 1](https://example.com/figure1.png)

**Figure 1.** The $\gamma\Upsilon(1S)$ invariant mass distribution for selected $e^+e^- \rightarrow \pi^+\pi^-\pi^0\gamma\Upsilon(1S)$ candidate events. The shaded histogram is from normalized $\pi^0$-sideband events. The fit to the $\gamma\Upsilon(1S)$ invariant mass spectrum is described in the text. The solid curves are the best fit for the total fit and background shape; the dash-dotted, dashed and dotted curves represent the $\chi_{b0}$, $\chi_{b1}$ and $\chi_{b2}$ signals, respectively.

An unbinned extended maximum likelihood fit is applied to
the $\gamma \Upsilon(1S)$ mass spectrum with Crystal Ball functions \cite{28} (parameters being fixed to the values from the fits to $\gamma \Upsilon(1S)$ mass spectra from MC signal samples) as $\chi_{bJ}$ signal shapes and a first-order polynomial function as a background shape. Figure 1 shows the fit results.

The statistical significance of the signal is estimated from the difference of the logarithmic likelihoods \cite{29}, \(-2 \ln \left( \frac{L_0}{L_{\text{max}}} \right)\), where $L_0$ and $L_{\text{max}}$ are the likelihoods of the fits without and with a signal component, respectively, taking the difference in the number of degrees of freedom ($\Delta\text{dof} = 1$) in the fits into account. The signal significances of $\chi_{b1}$ and $\chi_{b2}$ are 12$\sigma$ and 5.9$\sigma$ with systematic uncertainties included, while for the $\chi_{b0}$ the signal significance is only 1.0$\sigma$.

The fit results including the signal yield, detection efficiency, signal significance, and the calculated Born cross section for each mode are summarized in Table I. The Born cross section is calculated using $\sigma_B = N \cdot \left| 1 - \Pi \right|^2 / L \cdot \mathcal{F}_{\text{int}} \cdot \epsilon_1 \cdot (1 + \delta)$, where $N$ is the signal yield, $L$ is the integrated luminosity, $\mathcal{F}_{\text{int}}$ is the product of the branching fractions of the intermediate states to the reconstructed final states, $\epsilon_1$ is the corresponding detection efficiency, $1 + \delta$ is the radiative correction factor and $|1 - \Pi|^2$ is the vacuum polarization factor. In the MC simulation, trigger efficiency is included, and initial state radiation is taken into account by assuming the cross sections follow the $\Upsilon(10860)$ line shape with a zero non-resonant contribution \cite{23}. The radiative correction factor $1 + \delta$ is 0.65 $\pm$ 0.05 calculated using the formulae in Ref. \cite{30}; the value of $|1 - \Pi(s)|^2$ is 0.929 \cite{31}. The calculated branching fraction $B$ for each mode is also shown in Table I, where the total number of $\Upsilon(10860)$ events is $(4.02 \pm 0.20) \times 10^7$ using $\sigma_{b\bar{b}} \equiv \sigma(e^+e^- \rightarrow b\bar{b}) = (0.340 \pm 0.016)$ nb \cite{32} and assuming all the $b\bar{b}$ events are from $\Upsilon(10860)$ resonance decays \cite{33}.

We determine a Bayesian 90% confidence level (C.L.) upper limit on the number of $\chi_{b0}$ signal events ($N_{\text{sig}}$) by finding the value $N_{\text{UL}}$ such that $\int_{N_{\text{UL}}}^{N_{\text{sig}}} \mathcal{L} \cdot dN_{\text{sig}} / \int_{0}^{N_{\text{UL}}} \mathcal{L} \cdot dN_{\text{sig}} = 0.90$, where $N_{\text{sig}}$ is the number of $\chi_{b0}$ signal events and $\mathcal{L}$ is the value of the likelihood as a function of $N_{\text{sig}}$. To take into account the systematic uncertainty, the above likelihood is convolved with a Gaussian function whose width equals the total systematic uncertainty. The upper limit on the number of $\chi_{b0}$ signal events is 13.6 at 90% C.L.

Figure 2(a) shows the scatter plot of $M(\pi^+\pi^-\pi^0)$ versus $M(\gamma \Upsilon(1S))$. Besides the clear $\omega$ signal in the $\chi_{bJ}$ mass region, there is an obvious accumulation of events above the $\omega$ mass region. Hereinafter, we denote these events as $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}$ events.

An unbinned two-dimensional (2D) extended maximum likelihood fit to the $\pi^+\pi^-\pi^0$ versus $\gamma \Upsilon(1S)$ mass distributions is applied to extract the $\omega\chi_{bJ}$ and $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}\chi_{bJ}$ yields. In this fit, Crystal Ball functions (parameters being fixed to the values from the fits to $\gamma \Upsilon(1S)$ mass spectra from MC signal samples) are used for the $\chi_{bJ}$ signal shapes, a Breit–Wigner function and an Argus function \cite{34} (both are convolved with a Gaussian resolution function) represent the $\omega$ and $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}$ shapes, respectively, and a linear function is used for the backgrounds. The Gaussian resolution function is obtained from MC simulation.

Figures 2(b–d) show the $\pi^+\pi^-\pi^0$ mass projection for 9.8 GeV/c$^2 < M(\gamma \Upsilon(1S)) < 10$ GeV/c$^2$, and the $\gamma \Upsilon(1S)$ mass projection within and outside the $\omega$ signal region (0.753 GeV/c$^2 < M(\pi^+\pi^-\pi^0) < 0.813$ GeV/c$^2$), where the shaded histograms are from the normalized $\pi^0$ sideband events. Clear $\chi_{b1}$ and $\chi_{b2}$ signals can be seen in the $\gamma \Upsilon(1S)$ invariant mass spectrum, while no excess of $\chi_{b0}$ events above expected backgrounds is observed. The fit results with the calculated Born cross sections and branching fractions are summarized in Table I.
estimated by comparing control samples of $\eta \to \pi^0\pi^0\pi^0$ and $\eta \to \pi^+\pi^-\pi^0$ decays in data and amounts to 2.2%. The uncertainty due to the 5C kinematic fit is 4.2% obtained by comparing the final results with or without using this fit. A 3.0% systematic error is assigned to the trigger uncertainty. Errors on the branching fractions of the intermediate states are taken from Ref. [23]. For the cross section measurement, the uncertainty of the total luminosity is 1.4%. For the branching fraction measurement, the uncertainty on the total number of $\Upsilon(10860)$ events is 4.9%, which incorporates the uncertainty of the cross section $\sigma(e^+e^- \to bb)$ (4.7%) [32]. The uncertainty on the radiative correction factor is 7.7% due to the uncertainties of the $\Upsilon(10860)$ resonant parameters. The uncertainty due to limited MC statistics is at most 1.0%. We estimate the systematic errors associated with the fitting procedure by changing the order of the background polynomial and the range of the fit, and comparing the fit results without a $\chi^0$ component. Finally, the uncertainties due to the fitting procedure are 3.9%, 1.6%, 3.2% for $\pi^+\pi^-\pi^0\chi_{bJ}$ $J = 0, 1, 2$, respectively. For the $\omega\chi_{bJ}$ processes, the uncertainties in the yields of $\chi_{bJ}$ events due to the 2D fit model are estimated. We modify the background shape to a constant or a second-order polynomial and the parametrization description for the $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}$ events to a free Breit-Wigner function to check the results stability with respect to the fit model. The maximum differences compared with the nominal results are taken as the systematic uncertainties and are 15.8%, 4.4% and 21.7%, for $\omega\chi_{bJ}$, and 32.8%, 14.1% and 42.3%, for $(\pi^+\pi^-\pi^0)_{\text{non-}\omega\chi_{bJ}}$, $J = 0, 1, 2$, respectively. For $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}$, an uncertainty due to the unknown spin-parity of the $(\pi^+\pi^-\pi^0)_{\text{non-}\omega}$ system (6.0%) is also included. Assuming all the sources are independent and adding them in quadrature, the final total systematic uncertainties for the studied modes are summarized in Table I.

We search for the $X_b(3872)$-like state $X_b$ in the process $e^+e^- \to \gamma X_b$ with $X_b \to \omega\Upsilon(1S)$ at $\sqrt{s} = 10.867$ GeV. The selection criteria are the same as in $e^+e^- \to \pi^+\pi^-\pi^0\chi_{bJ}$. Figure 3 shows the $\omega\Upsilon(1S)$ invariant mass distribution with the requirement of $M(\pi^+\pi^-\pi^0)$ within the $\omega$ signal region; we search for the $X_b$ from 10.55 to 10.65 GeV/$c^2$. The dots with error bars are from data, the solid histogram is from the normalized contribution of $e^+e^- \to \omega\chi_{bJ}$ ($J = 0, 1, 2$) and the shaded histogram is from the normalized $\omega$ mass sideband, defined as 0.54 GeV/$c^2 < M(\pi^+\pi^-\pi^0) < 0.72$ GeV/$c^2$. No obvious $X_b$ signal is observed after applying all the event selection criteria.

An unbinned extended maximum likelihood fit to the $\omega\Upsilon(1S)$ mass distribution is applied, where the signal shape is obtained from MC simulation and the background is parameterized as a first-order polynomial. From the fit, we obtain $-0.4 \pm 2.0 X_b$ signal events with a mass at 10.6 GeV/$c^2$. The upper limit on the yield of the $X_b$ signal events is 4.0 at 90% C.L. with systematic uncertainty included. The dashed histogram in Fig. 3 shows the upper limit on the yield of $X_b$ signal events.

With the detection efficiency of 8.1% and assuming that the observed signals come from $\Upsilon(10860)$ decays, we obtain the product branching fraction $B(\Upsilon(10860) \to \gamma X_b)B(X_b \to \omega\Upsilon(1S)) < 2.9 \times 10^{-5}$ at 90% C.L. The systematic uncertainties on the above branching fraction measurement are almost the same as in $e^+e^- \to \omega\chi_{bJ}$, except for the fit uncertainty (29%) and total error on the branching fractions of the intermediate states (3.2%). Assuming all the sources are independent and adding them in quadrature, we obtain a total systematic uncertainty of 31%. Using the aforementioned method, 90% confidence level upper limits on the product branching fraction $B(\Upsilon(10860) \to \gamma X_b)B(X_b \to \omega\Upsilon(1S))$ vary smoothly from $2.6 \times 10^{-5}$ to $3.8 \times 10^{-5}$ between 10.55 and 10.65 GeV/$c^2$.

In summary, using the 118 fb$^{-1}$ $\Upsilon(10860)$ data sample collected with Belle, the processes $e^+e^- \to \pi^+\pi^-\pi^0\chi_{bJ}$ and $\omega\chi_{bJ}$ ($J = 0, 1, 2$) are studied. We observe clear $\pi^+\pi^-\pi^0\chi_{b1}$ and $\pi^+\pi^-\pi^0\chi_{b2}$ signals, while no significant $\pi^+\pi^-\pi^0\chi_{b0}$ signal is found. In the $\pi^+\pi^-\pi^0$ invariant mass spectrum, besides a clear $\omega$ signal, significant non-$\omega$ signals are also observed. The $\omega\chi_{b1}$ signal and indication for $\omega\chi_{b2}$ are found, while no significant signal of $\omega\chi_{b0}$ can be seen. All the results are summarized in Table I. The measured branch-

| Mode | Yield | $\Sigma(\sigma)$ | $\epsilon(\%)$ | $\sigma_B$(pb) | $B(10^{-3})$ | $[\Gamma^{\omega\chi_{bJ}}]_{1\sigma}(\%)$ | $[\Gamma^{\omega\chi_{bJ}}]_{2\sigma}(\%)$ |

Figure 3. The $\omega \Upsilon(1S)$ invariant mass distribution. The dots with error bars are from data, the solid histogram is from the normalized contribution of $e^+e^-\rightarrow \omega \chi_{b1}$ ($J = 0, 1, 2$) from MC simulation and the shaded histogram is from normalized $\omega$ mass sideband events. The dashed histogram is from the MC signal sample $e^+e^-\rightarrow \gamma X_b \rightarrow \gamma \omega \Upsilon(1S) \rightarrow \gamma \pi^+\pi^-\pi^0\ell^+\ell^-$ at $\sqrt{s} = 10.867$ GeV with $X_b$ mass fixed at 10.6 GeV/$c^2$ and yield fixed at the upper limit at 90% C.L.

The possible cascade branching fractions of $\Upsilon(10860) \rightarrow \pi^+\pi^-\pi^0\chi_{b1}$ and $\pi^+\pi^-\pi^0\chi_{b2}$ are large and at the same order as the processes $\Upsilon(10860) \rightarrow \pi^+\pi^-\chi_{m(S)}$ ($m = 1, 2, 3$). This is the first observation of hadronic transitions between the $\Upsilon(10860)$ and $\chi_{b1, b2}$ bottomonium states that provides important information for understanding QCD dynamics. The ratio of the branching fractions of $\Upsilon(10860)$ decays shows the mixing of the $\Upsilon(10860)$ to $\omega \chi_b$ and the cross sections of $e^+e^-\rightarrow \omega \chi_b$ and $\omega \chi_{b1}$ are 0.38±0.16(stat.)±0.09(syst.), where the common systematic uncertainties cancel. It is significantly lower than the expectation of 1.57 from the heavy quark symmetry [35, 36]. For $\pi^+\pi^-\pi^0$ non-ω events, such ratio is 1.20±0.55(stat.)±0.65(syst.). We also search for the $X(3872)$-like state, $X_b$ with a hidden $b\bar{b}$ component decaying into $\omega \Upsilon(1S)$, in $\Upsilon(10860)$ radiative decay. No significant signal is observed for such a state with mass between 10.55 and 10.65 GeV/$c^2$.

We thank the KEKB group for excellent operation of the accelerator; the KEK cryogenics group for efficient solenoid cooling; and the KEK computer group, the NII, and the KEK cryogenics group for efficient solenoid cooling. We acknowledge support from MEXT, JSPS and PNNL/EMSL for valuable computing and SINET4 network operations; and the KEK computer group, the NII, and the KEK accelerator; the KEK cryogenics group for efficient solenoid cooling. We also search for the $X(3872)$-like state, $X_b$ with a hidden $b\bar{b}$ component decaying into $\omega \Upsilon(1S)$, in $\Upsilon(10860)$ radiative decay. No significant signal is observed for such a state with mass between 10.55 and 10.65 GeV/$c^2$.

Note added.– After preliminary results were reported at the international conferences, a few theoretical models have been developed to interpret the data: the possible cascade process $\Upsilon(10860) \rightarrow \pi Z_b \rightarrow \pi\rho\chi_b$ in $(\pi^+\pi^-\pi^0)$ non-ω $\chi_b$ events [37]; a molecular component in $\Upsilon(10860)$ wave-function [37] or an S- and D-wave mixing for the observed heavy quark symmetry violation between $\omega \chi_{b1}$ and $\omega \chi_{b2}$ [38]; and hadronic loop effect for the large branching fractions measured [38].

[33] In case there is a non-$\Upsilon(10860)$ resonance contribution in the $b\bar{b}$ cross section, the definition of the branching fraction $B$ is equivalent to the ratio of the two cross sections, i.e., $B = \frac{\sigma_{\text{vis}}}{\sigma_{b\bar{b}}} = \frac{N}{(L \cdot B_{\text{int}} \cdot \varepsilon \cdot \sigma_{b\bar{b}})}$, where $\sigma_{\text{vis}} (= N/(L \cdot B_{\text{int}} \cdot \varepsilon))$ is the visible cross section.
